ORIGINAL ARTICLES.

A SUCCESSFUL CASE OF GASTROTOMY, WITH CRITICAL REMARKS.

BY AUGUSTUS C. BERNAYS, A.M., M.D. HEID., M.R.C.S., PROFESSOR OF ANATOMY IN ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS.

THERE are numerous cases of the accidental or foolhardy swallowing of foreign substances recorded in the literature of medicine. Almost every physician has met one or more cases in his own practice. The vast majority of these objects are either ejected from the stomach by vomiting or pass through the intestinal canal without causing trouble or inconvenience. Among objects which have been known to pass off in this manner we may enumerate the following motley list: All kinds of fruit kernels, buttons, coins, nails and tacks, needles and pins, hairpins, articles of jewelry and rings, chessmen, checkers, dominoes, pieces of wood and corks, even small medicine bottles, a live mouse, lead bullets, etc. In a small number of this class the foreign body was found engaged in some part of the intestinal canal, where it caused ulceration and perforation, which was followed by peritonitis and death. In other still rarer cases, the foreign body has made its way to the surface by ulceration, which followed the path of inflammatory adhesions, and resulted in a natural cure.

The following pages will be devoted to the study and consideration of a different, rarer, and much more serious class of cases. We have recorded in the literature of medicine of all countries twenty-eight cases where foreign bodies were swallowed, of such size and shape that they could not possibly leave the stomach *per vias naturales*, either to be vomited up or to pass down and out. These cases were followed by the gravest symptoms, and sooner or later threatened to destroy the life of the patients by the continued irritation of the stomach which they caused. In an article by Credé, of Dresden, I found a table which was most carefully compiled by Dr. Koch, who searched the entire literature, and by studying the original memoirs has succeeded in giving us all the authentic cases in a convenient form for reference.

This paper will consider only the operation of gastrotomy where the stomach is free from adhesions and where the peritoneal cavity is opened before reaching the stomach. I consider it altogether unlikely that, under our present advanced surgical technique, and knowing the excellent prognosis which early gastrotomy offers, the removal of a foreign body from the stomach will be put off so long that adhesions will have time to form. The history of surgery records only twelve well-authenticated cases of this operation, and it was my good fortune to perform successfully the thirteenth.

CASE.—On the night of November 17, 1886, I was hastily summoned by Dr. Hugh Kinner to see a patient who had swallowed a table-knife. He was a healthy man, thirty-eight years of age, and had been entertaining his wife and children with tricks. He is an expert in the so-called sword-swallower's trick, having often in convivial circles introduced pokers, walking canes, the handles of kitchen utensils, and other long, smooth objects into his œsophagus. On this memorable evening, not having any other suitable instrument within easy reach, he took up an ordinary table-knife, a little more than nine and a quarter inches long, and quickly pushed it down into his gullet, the handle foremost. He removed his fingers from the blade for a moment, intending to hold the latter with his teeth. Just at this time, he afterward explained to me, something pulled the knife downward, and a few moments later it entered his stomach. He has told me since that the pain was not so great when he could keep quiet, and that his screams were due to his fright. When I entered the room the patient was having a spell of vomiting, which was repeated every minute, and there is no doubt that this paroxysmal vomiting caused him great pain. He had made up his mind that he had to die, and at first refused to permit an operation, on the grounds that he would die anyhow, and asked me for some morphine. Dr. Kinner and I, however, persuaded him in a few moments to get on an improvised operating-table, which Dr. Barck and Dr. E. Hauck, whom I had invited to come with me, had prepared. Dr. Barck kindly administered the chloroform. Less than one hour had passed since the knife had been swallowed. but having witnessed the violent attacks of vomiting I had serious misgivings, and thought that the stomach might have been perforated or at least seriously injured.

The patient had a wonderfully quiet narcosis which was easily kept up, one-third of a grain of morphine having been administered by hypodermatic injection simultaneously with the chloroform. The patient did not vomit during the entire operation, nor did the stomach show a single contraction, although it contained some beer and the remnants of a light supper, besides the knife.

I made an incision in the linea alba, five inches long, midway between the ensiform process and the umbilicus. The fascia transversalis was represented by a thick layer of fat. After opening the peritoneum, I introduced my hand into the abdomen and readily found the knife, which had assumed a transverse position so that the handle was situated near the pylorus, and the blade was in the fundus of the stomach, a little to the left of the vertebral column, exactly at the so-called angle of the ninth or

tenth rib (see figure). I rapidly felt over all sides of the stomach and assured myself that there was no perforation. I then turned the pyloric end of the stomach toward the incision, and, grasping the

handle of the knife, conducted it out of the abdominal incision, covered by the anterior wall of the stomach. The handle of the knife pushed the walls of the stomach out of the incision, and formed the centre-pole of a tent of which the stomach was the canvas. Next, I grasped the stomach with two "army" bullet forceps (Hegar's Kugelzange) one inch apart on either side of the knife-handle. I then made a straight incision between the forceps not over five-eighths of an inch in length, through which I extracted the knife with my fingers, after having pushed the stomach back on the handle one-half inch, so as to permit me to grasp the latter firmly. Not a drop of the contents of the stomach escaped; in fact, the incision was so small that as the knife was extracted all gastric fluids which might have adhered to it were scraped off.

By far the most interesting part of the operation, surgically speaking, was the suture of the small incision in the stomach. I employed exactly the same method which has served me well in one case of circular resection of the ileum and in two cases of suture of the gall-bladder. An accurate description of this suture with illustrations will be found in *Chips from a Surgeon's Workshop*, Chip No. IX., first published in the *Weekly Medical Review*, under the title of "Ideal Cholecystotomy," October 31, 1885. This method of suture is very similar to the one which was first employed by Billroth and Czerny in their operations of resection of the pylorus. I used the very thinnest kind of catgut for the first five sutures, which were only simple interrupted stitches embracing the peritoneum, muscularis, and perhaps some little of the submucosa (it was my intention to leave out the mucosa in all but one stitch). These were tied and cut very close. Although they were less than one-eighth of an inch apart the mucosa showed a tendency to interpose itself between the stitches, and great care was necessary to prevent this occurrence. I think this little accident would cause a failure of union, and, unless a row of Lembert sutures produced sufficient effusion of lymph to keep the stomach closed, the result would be fatal. Over the row of five stitches, which we intended to produce a direct union of the cut edges, a second row of eight Lembert sutures was applied. I used the very thinnest kind of Chinese silk, such as I was taught to use in harelip operations by the genial Gustave Simon, of Heidelberg. This silk is twisted, and, in my estimation, is much superior to the braided silk. It is very hard, and becomes but little thicker after being left in the tissues for several days. It differs in this respect from the braided or any other silk which has been treated by antiseptic fluids. I used the silk dry, as I always do. I purify it by exposing it to a dry heat of about 200° C. for several hours in an oven. These eight sutures completely buried out of sight the five catgut sutures, and left a smooth stomach covered all over by peritoneum. The sutures caused but very little bleeding, and the stomach was dropped back into its place immediately.

The last act of the operation was the suture of the external incision. This was closed by means of ten sutures which embraced all the layers of the abdominal parietes and about eight superficial stitches. A layer of bichloride gauze, made in Milwaukee, which is packed in such a manner that it is continually moist, was used over the incision, and this covered by a sheet of rubber tissue. The dressing was held in place by a ten-yard rubber elastic web-bandage, and was not touched for five days. The patient bore the operation well, the entire proceeding lasting but one hour. The patient was put to bed, and slept soundly all night.

The after-treatment was conducted by Dr. Kinner, who insisted on a very strict *régime*. He allowed the patient only a spoonful of water every two or three hours during the first four days. He was given large nutrient enemata of peptonized milk and beef tea. Wine and whiskey were also given per rectum, as it was feared that he could not bear the sudden withdrawal of all alcoholics. He was also given a hypodermatic injection of morphine every evening. He had no vomiting during the time he was confined to his bed, and only complained of a feeling of nausea when I introduced the thermometer into his mouth.

The only time that there was a rise of temperature deserving of mention was on the evening of the second day, when it reached 100° F. His pulse never reached 90, and pulse as well as temperature was permanently normal after the third day. I removed all the stitches on the fifth day; there was complete union by first intention. Hoffmann began to eat soups and beef-broth after the fifth day, and ate his usual fare after the tenth day, when he left his bed. I discharged him from treatment on the fourteenth day.

The table which is appended here requires no ex-

TABLE OF GASTROTOMIES FOR THE REMOVAL OF FOREIGN BODIES, IN WHICH THERE EXISTED NO ADHESIONS BETWEEN THE STOMACH AND ABDOMINAL WALLS.

Case, Sex, and Age.	Operator.	Foreign Body.	Time in stomach	Condition before Operation.	Operation	After-treatment and Remarks.	Final Result.
I. M. 22	SCHWAB, B.Klinger's Neues Mag f Aerzte, F. xvi., 1798, p. 67. Reprint Hin Wach., No. 7, 1897. Hartland's Mirs and Notes Princess, 1804.	Table Knife 6¾ in. long, 2·6 in. broad.	41 days	No serious inconvenience.	Incision 15 in. below and parallel to 7th rib left side. Stomach pulled out by means of a curved needle, and the right point of swallowed knife. The incision stapled shut and knife hard been extracted. Abdominal incision closed with five sutures; operation without anæsthetics.	Fat meal and water given on 2nd day. Sutures removed on 7th day. Healthy urine and stools on 9th to 10th days. Wound washed with warm water but dressed for two days, in which time wound entirely healed.	Patient remained perfectly well for 11 years, when last heard of.
II. F. 22	HEARNS, Ont. Diss continua canum gastrotomeæ est Lugdun, Batavorum, 1755.	Silver fork, 8½ in. long, and some fragments of crockery, triangular in shape, largest piece 2cm. in its greatest length.	2 days	Very weak; great difficulty in swallowing. Diagnosis contained by examination of region of the stomach.	Etherized. Incision in linea alba, 3 in. Stomach drawn up with two forceps and opening made into anterior wall, 1 in. in length, causing considerable hemorrhage. Search for fork and crockery very troublesome. Stomach was closed by 3 sutures, wire embedding out of lowermost of the abdominal incision, which was closed by ordinary suture.	Vomiting of a greenish fluid pain and tympanites during the first days. Feeble and high pulse on 2nd day. Death on 3rd day.	Post mortem, showed plastic material which caused adhesions between stomach, liver and abdominal parietes. Gastric incision easily closed. Stomach much distended. Upper third of œsophagus much lacerated and pervorted opposite Cysix. A pus sinus along lobe of thyroid.
III. M. 27	BELL, The American Journal of the Medical Sciences, July, 1825, p. 242.	Bar of lead 3 inches long, one-fifth inch in diameter	9 days	No serious inconvenience at the beginning, on the fifth day vomiting and great prostration. Palpation failed to reveal the presence of a foreign body	An incision beginning at second false rib, 4 in in length, and at a distance to the left of the umbilicus. A small incision was made into the stomach upon the bar. Bead after extraction. Contraction of stomach closed the opening. Prolapse of some of the intestines during the operation. Abdomen closed by interrupted suture	Symptoms of gastritis immediately after operation. Hypodermic injections given every hour. Patient discharged on two weeks	Complete recovery
IV. M. 18	LATTÉ, Gazette Hebdomad. Dep. de Sciences, and (MALGAIGNE, 1878, p. 274	Five-tined German silver fork	2 yrs and 10 days	No serious inconvenience for six months. Later on attacks of syncope and symptoms of severe gastralgia came on.	Futile attempts were made to cause adhesion between stomach and parietes, by means of external applications. Laparotomy, parallel to 7th rib, incision less than 2 in. Stomach pulled out by forceps and attached to abdominal incision before opening. Fork extracted with polypus forceps.	A strong collodion corset was applied to the abdomen. Solid food after 3 days. Wound healed kindly, leaving a gastric fistula. Patient discharged on 18th day, a small gastric fistula remaining (quickly gastrotomy)	Recovery. It is not stated how long the fistula persisted.
V. M. 17	KECHER, Correspondenz Blatt für Schweizer Aerzte, 1880, Nos. 23 and 24.	Piece of a broken instrument (a perforating sheep with bucket)	1	No serious inconvenience.	Oblique incision 7 inch from edge of ribs. Stomach drawn up by two pocket thread. Incision in stomach, over 1 inch long, was closed by 2 Lembert sutures	Corded 1 c., no fever. Union by first intention	Complete recovery.
VI. M. 19	OSSENBRUGGEN, Wiener medizinische Wochenschrift, 1877, Nos. 51 and 52.	Broken sword-blade 3 cm. in its largest Point rounded off; broken end rough and jagged.	2 days	Great pain. Emetics and attacks of syncope first day only. Later symptoms of acute gastritis came on.	Knife extracted with great difficulty after a large opening had been made in stomach.	Death in two days, due to septic peritonitis.	Post mortem showed that stomach had been perforated by the point, and œsophagus by broken end.
VII F. 17	SCHOONDEN, Langenbeck's Archiv für Chirurgie, B. xxiv. p. 629.	Hair tumor, remained very hard.	About 4 years	Vomiting, a freely movable tumor in the left hypochondrium could be felt.	Laparotomy in linea alba. Tumor lying loose, incision in stomach large enough to admit the curvatures. Wound closed by 66 Mackenzie sutures.	Union by first intention. In three weeks she was discharged.	Complete recovery.
VIII F. 17	THORNTON, Lancet, 1884, No. 1.	Hair tumor, weighing 2¼ lbs	Several years.	Tumor tilled entire cavity of stomach. An abdominal tumor was revealed by palpation. Patient very much emaciated	Incision 5 in. Stomach pulled out, and incision made into stomach 2 in. Three rows of sutures used.	A sponge was left in the abdominal cavity, but was taken out on 7th day by a probing instrument. Healthy parietes and uneventful fever.	Complete recovery.
IX F. 19	BILLROTH, Von Hacker, Magen Operationen in Prof. Billroth's Klinik, von 1880 bis 1892. Vienna, Leipzig & Berlin, 1893.	Artificial denture, seventeen teeth.	7 days.	But little inconvenience	Incision 4½ in. along border of ribs and beginning at ensiform cartilage. Stomach held by two loops of thread and denture extracted through a small opening, which was closed by a number of ordinary external, interrupted sutures, and then by 2 rows of Lembert sutures.	The healing was uncomplicated by febrile symptoms. Left hospital 3 weeks after operation.	Complete recovery.
X M. 28	CZERNY, Von Langenbeck's Archiv für Chirurgie, B. xxxiii. p. 554, 1886.	Hard rubber denture, eight teeth and clasps.	15 days	Vomiting and insomnia accompanied by great nervous excitement.	Oblique incision, 5 in. parallel to 7th rib and ligamenta gastrocolica cardiaca. Foreign body was found near pylorus. Incision in stomach 2 in. Three rows of sutures used.	No vomiting or febrile disturbance.	Complete recovery.
XI. M. 28	LEBLANC, Progrès Médical, Année 4, 1876.	A fork	A few days	But little inconvenience.	Transverse incision, 7 c.m. long. Stomach pulled out by two needles, incision 3 c.m. long. Fork pulled out with forceps. Wound sutured in three layers. Stomach repaired, external wound closed by 6 sutures	Union by first intention	Complete recovery.
XII M. 27	RICHARDSON, Brit. Med. and Surg. Journ., Aug. 24, 1878.	Artificial denture, 11 teeth and clasps	4 months	Greatly emaciated, foreign body was situated in the lower part of the œsophagus, just above the cardia	Oblique incision parallel to ribs. Stomach pulled out, and an incision made into anterior wall. Foreign body found and forceps. Extraction of forceps, body with fingers, considerable difficulty experienced before it could be brought through the cardia and into the stomach. Mucous membrane united by accentuine silk suture. The peritoneal surface united by fine silk Lembert sutures.	Union by first intention, with exception of some stitch hole suppuration	Complete recovery.
XIII. F. 38	BENNAYS, The Medical News, Jan. 1, 1897.	Silver plated, metal-handled table knife, 9¼ inches long	Several months	Frequent paroxysms of pain in the region of the stomach, which, however, did not produce emesis.	Incision in linea alba, between xiphoid cartilage and umbilicus. Stomach drawn up by two "Allis" Indefatigable forceps. Incision about 2 in., upon the handle of the knife. Gastric wound closed by two interrupted catgut sutures and then buried by 8 Lembert stitches, in one row. 18 sutures closed the abdominal incision.	Fed per rectum, a little water allowed. No fever and no vomiting. Patient up and about ten days after operation.	Complete recovery.

planation. Nearly every one of the cases has some peculiarities of its own. The whole number of observations is so small that general deductions cannot be drawn. It is evident that these operations will always be among the rarest in surgery, only thirteen cases having been recorded in two hundred and fifty-one years. I think that they will be performed more frequently, since we have recognized that the rate of mortality is much smaller than was formerly expected. Credé says: "Formerly this class of patients perished almost without exception, because a successful result was not expected from surgical interference." The progress of surgery compels us to attempt relief in all these cases. The rate of mortality as computed from the above table is only ten per cent. It is safe to predict that it will be much reduced by future operations.

The distinctive features of my case, when compared with those previously recorded may be enumerated as follows. The length of time which the knife was allowed to remain in the stomach in my case is, by far, shorter than in any of the others.

The knife which was swallowed seems to be the longest foreign body which has been successfully removed by gastrotomy. The mishap occurred in the only imaginable way that it could happen, namely, by being deliberately pushed into the œsophagus, with the intention of performing a curious feat. Four of the ten cases previously recorded seem to have happened in this way.

The manner in which I performed the operation differs but little from the method employed by Billroth, Credé, and Kocher. These three operators chose the oblique incision parallel to the free border of the ribs. I can see no good reason for this, and searched the literature of the subject in vain for a *raisonnement* on this point. I have always been partial to the incision in the linea alba. In two out of four cases where I opened the abdominal cavity, the diagnosis being cholelithiasis, I made the oblique cut and in both cases found no gall-stones. In the other two cases the incision was made in the linea alba and gall-stones were found. In six cases of carcinoma ventriculi, where I intended to resect the stomach, I made the incision in the linea alba. I had no difficulty in rolling out the stomach, although in some the tumors were quite large. In all of these cases I had to close the abdominal incision, because the tumors were inoperable. The explorative laparotomy had no effect on the progress of the disease either for good or for evil.

A careful study of the cases recorded shows the curious fact that no two operators, thus far, have treated the incision in the stomach by the same means, excepting Cases I. and III., which were not treated at all, the incisions in the stomach, in both cases, being simply left alone to get along as best they might, aided by the natural contraction of the coats of the stomach. Both these cases recovered. We have reason to assume that the incisions in both cases were little more than punctures. At the present day we would apply one, two, or three Lembert sutures, even over a puncture. Where, in the last seven cases sutures were employed according to the principles of modern surgery, there is no uniformity of detail. Neither the materials used for the sutures, nor the manner of their application, are alike in all the cases. The operations were all successful, excepting the case of Gussenbauer, and in this one the autopsy clearly accounted for the failure. Under these circumstances I will not presume to recommend any particular kind of suture. It seems to me that the material of which the suture is made is of the least importance. Success depends here, as in all sutures which are designed to achieve primary healing, upon putting together only such tissues as are denuded of epithelium, or by virtue of their histological elements are capable of becoming adherent under the influence of a limited irritation.

I cannot allow this opportunity to pass by, without cautioning against the use of the continued suture under circumstances where tension upon the edges which we desire to unite may possibly occur. This practice cannot be too strenuously condemned. It is directly opposed to securing union. It does not fulfil the chief indication, viz., to keep the parts accurately approximated by an evenly distributed pressure.

The fact that my patient never vomited from the moment that anæsthesia began up to his complete recovery, remains as inexplicable to me as it does to Credé, who observed the same circumstance in his case.

In answer to the question whether the operation was performed with antiseptic precautions, I would answer that the room was not aseptic, the assistants were practitioners of medicine who were not especially disinfected for the occasion. I had taken a bath some three hours before the operation, but was not so carefully prepared as is my custom before an ovariotomy. The patient was in no wise prepared beyond having his abdomen hurriedly cleansed before I made the incision. The sponges and fluids used, as well as my instruments, were aseptic.

A REMARKABLE CASE OF LEAD POISONING.

BY [illegible] M. D.,
[illegible]

J. C., a maiden lady, aged forty, had had no illness of moment until two years ago. Previous to this time her health had been excellent. She had taken part in the ordinary duties of a household, her appetite had been good, and she had been able "not only to do her own work but that of others also." Within the last two years, however, she had suffered a gradual and increasing loss of strength. She had lost her appetite, her weight had diminished, and she had grown very nervous. Rest, tonics, and travel had done her no good, and she finally presented herself to the writer in a very disheartened frame of mind.

She presented the following symptoms: Along with her great nervousness and loss of appetite she suffered markedly from insomnia. She had also a constant itching of the skin, which at night became almost intolerable. At various places about the face and neck and under arms, small patches of eczema existed. The itching, however, was not confined to these patches, but appeared to be general. Her

weakness was extreme, very slight exertion causing fatigue. She also complained of intense backache, and the spine was decidedly tender to pressure. The knee-jerk was increased. In searching for motor disturbances, nothing was noted. The patient stated, however, that she had occasionally slight cramp in the flexor muscles of the right forearm. There was, too, no impairement of sensation anywhere, although the patient complained of a numb feeling in the right arm.

The case thus far presented little else than symptoms of a general neurasthenia. The fact, however, of her previous good health and of the absence of any mental or physical strain preceding the trouble, indicated some deep-lying cause as being at the bottom of this profound disturbance of nutrition.

Further questioning elicited a history of indigestion, together with constipation, although the latter was not especially marked. She also complained of an irregularly recurring pain or cramp in the abdomen. This evidently did not occupy a very prominent part in her notion of her trouble, and had never been severe enough to suggest the use of anodynes. An examination of the gums revealed a faint blue line in the neighborhood of one of the lower canines. It was so faint, however, as to render its significance doubtful.

In order to decide absolutely the question of lead poisoning, an examination of the urine was determined upon, and a quantitative analysis was made by Dr. John Marshall, Demonstrator of Chemistry in the University of Pennsylvania. He made the following report: "I employed 400 cubic centimetres of the urine, and obtained a globule of lead which weighs 5.2 milligrammes (0.0052), equal to 0.0013 per cent. of metallic lead. This is by far the largest quantity of lead I have ever found in an equal amount of urine,—an enormous percentage as such things go."

Dr. Marshall also kindly gave me the results of several other quantitative analyses of the urine of cases of lead poisoning, which are as follows:

In one case he found, in two litres of urine, an amount of lead insufficient to weigh. In another he found 0.0002 per cent. of lead, and in still another only 0.00017 per cent. These results are, therefore, far below the amount in the present case.

Upon one occasion the patient brought a pillow-case upon which was a dark stain an inch and a half or more in diameter. She said that she had taken an afternoon nap, and that while asleep, some saliva had dribbled from the mouth, and that several days afterward the stain had turned dark. Dr. Marshall pronounced the stain as due to sulphide of lead. She also at another occasion brought with her a baby's sock which she had been knitting, and, strangely enough, the sock had, after a time, turned dark. This discoloration likewise proved to be due to sulphide of lead. She stated that for a time past all of her knitting had turned dark in a similar way. Some time—several days—had always elapsed before the stain made its appearance.

It should be stated that at one of her visits she had complained of a decided metallic taste.

The patient was placed upon iodide of potassium, in doses equalling a drachm a day. Rest, massage, and faradism were likewise employed. She bore the iodide remarkably well. The cramps of the bowel rapidly grew less, and finally disappeared, as did also the constipation. Curiously enough, however, the metallic taste became, for a time, more pronounced, as did also the itching of the skin. The patches of eczema too increased in size, and for a time constituted one of the most annoying features of the case.

However, the neurasthenic condition rapidly improved. Sleep, appetite, and general strength became decidedly better. After four months she had gained decidedly in flesh. The itching, too, though at first somewhat worse, had disappeared, as had also the metallic taste. She then, though still taking the iodide, took a trip to the country.

At present writing, some eight months after first presenting herself, she is convalescent from a severe cold. For about six weeks the iodide has been omitted. The trace of blue line upon the gums has entirely disappeared. The only symptoms present are rheumatoid or gouty pains in the muscles of the chest-wall, and a slight pain in the left hip. It is probable that these pains are dependent upon the attack of cold, but it is possible that they constitute an "after-clap" of the lead.

Regarding the source of the poison, the investigation, though diligent, was fruitless. The drinking water was analyzed with a negative result, as were, also, two samples of face powder, the only brands the patient had ever used. No hair-dye had ever been employed. Again, the patient said that some white silk that she had been using for years had a sweetish taste, and that she had been in the habit of biting off the ends; but an analysis of a sample likewise yielded a negative result. It should be stated, also, that none of the other members of her family, living presumably under the same conditions as herself, presented, so far as could be ascertained, any symptoms of lead-poisoning.

The remarkable features of the present case are, first, the enormous amount of lead present in the tissues; and, secondly, the paucity of *specific* lead symptoms. The *itching of the skin* also deserves particular attention, as it was probably directly dependent upon the excretion of the chloride of lead by the skin.

POISONING BY LEAD CHROMATE (CHROME YELLOW) USED FOR COLORING CAKES.

BY JOHN MARSHALL, M.D.,

DEMONSTRATOR OF CHEMISTRY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

I HAVE recently had occasion to examine samples of urine from patients manifestly suffering from lead poisoning, detecting lead in every case, and in whom I was able to eliminate all of the ordinary sources of poisoning from water, canned goods, and ordinary house supplies. In conversation with a large wholesale druggist, I accidentally learned that

chromate of lead had been purchased of him in considerable quantities by persons whom his clerks recognized as bakers. He was unable to furnish me with the names and addresses of these persons, and accordingly a search was instituted among the bakers in the neighborhood of his shop. In all twenty-six shops were visited, and samples of the yellowest cakes obtainable purchased; from eight of these shops, tea-buns, also, were purchased. These samples were subjected to the following treatment: The inner portions of each were dried, pulverized, and mixed with a ten per cent. solution of sodium hydrate (*free from iron*), placed in a test-tube and heated to about the boiling point. In the presence of lead chromate a brownish to black coloration is produced. This reaction is dependent upon the action of the sodium hydrate upon the albuminous materials in the cake, with a resultant liberation of sulphur, which unites with the alkali to form sodium sulphide, which latter reacts upon the lead chromate, which had been dissolved by the caustic alkali, to form (black) lead sulphide. The intensity of the coloration is, of course, dependent upon the quantity of the lead present. Care must be taken that the caustic soda is free from iron, otherwise black iron sulphide will, in any case, be formed. Iron present in the cake as a result of the use of rusted kettles or pans will not interfere with the test, only freshly precipitated ferric hydrate or iron in solution having such action.

A convenient modification of this test may be employed. The dried and pulverized cake may be gently warmed with sodium hydrate, in order to dissolve the lead chromate, without going so far as to decompose the albumen present. Either sodium sulphide or ammonium sulphide may now be added, and lead, if present, will be detected by a brownish or blackish coloration of lead sulphide. By either of these tests one one-hundredth of one per cent. of lead chromate may be detected in the dried and pulverized cake.

Only in cakes obtained from four out of the twenty-six shops visited was any lead found. In all four of these places lead was found in the tea-buns purchased, and in the bright yellow pound cakes obtained in three of these places it was also found. The tea-buns were pale yellow in color, and although special tests for chromium were not applied, it is to be taken for granted that the lead was present as the chromate, inasmuch as no incentive exists for the baker to introduce lead in any other form. As the chromate it, of course, replaces the far more expensive yolks of eggs.

It was learned that vegetable coloring matters were also largely employed, but on account of their relative high cost and low coloring intensity as compared with the metallic pigment they are viewed with less favor by the unscrupulous baker.

The use of lead chromate for coloring tea-buns is not recent. In England years ago it was used for that purpose, and very likely even at the present time such use is made of it in that country.

Mem. Am. Chem. Soc. [illegible] Univ. of Penna. [illegible]

A CASE OF SUDDEN DEATH FROM THE INTRODUCTION OF AN ASPIRATOR NEEDLE.

By J. C. REEVE, M.D.,

THE subject of this report was a man twenty-three years of age. He had been ill for six weeks under the care of Dr. W. J. Conklin, of Dayton, and latterly had been seen several times in consultation by Dr. J. H. Rodgers, of Springfield, Ohio, a relative. The leading symptoms of his illness had been fever, sometimes ranging up to 103.5°; chills, some of which were severe, but irregular as to time of recurrence; attacks of vomiting, and right dorsal decubitus. Examination showed enlargement of the liver, which increased notably toward the last, and there was tenderness of the epigastrium and right hypochondriac region. The diagnosis was abscess of the liver. I saw him, in consultation, on the 14th of December, concurred in the diagnosis, and gave full assent to the proposition to aspirate the liver. The time of operation was fixed on the following day. At the time appointed Dr. Conklin was engaged with an obstetrical case, and I was requested to operate, and proceeded to do so, Dr. Rodgers and Dr. H. C. Conklin being present. The particular time of operation had not been made known to the patient until after we entered the room. He did not seem at all alarmed, but asked if we would give him an anæsthetic. I told him that the insertion of the needle was too trifling a matter to need that, and as he expressed no anxiety or alarm, we did not resort to any local anæsthetic. He was, of course, feeble from a long and severe illness, but changed his position and assisted in raising his clothing. A point had been selected for the puncture a little over an inch to the right of the median line, and not quite two inches below the margin of the costal cartilages. While there was no bulging at this point, yet it was the seat of more pain and tenderness than elsewhere, and there was dulness on percussion all around. I took a medium sized needle of the aspirator and thrust it in at this point, upward and backward, to a depth of about three inches. As the stop-cock was turned, and I looked to see if pus appeared, my attention was attracted by the heavy breathing of the patient; I looked at his face, saw the head drawn to the left, the eyes turned and fixed, a slight convulsive tremor passed over his features, which bore the plainest impress of death. I found his pulse gone; no movement of his heart could be felt. After a brief interval of entire cessation of breathing, he drew one deep inspiration, which was the last manifestation of life. I should estimate the whole time from the puncture of the needle until he was gone at not over one minute and a half.

A partial post-mortem examination was made the next day. Upon opening the abdomen the liver was seen to be enlarged, reaching down to the level of the umbilicus. The puncture of the liver by the needle was plainly visible, surrounded by a small patch of ecchymosis. Upon lifting the organ up to remove it, an abscess of the right lobe gave way upon the under side near the centre, from which

eight or ten ounces of pus escaped. The heart was, in appearance, healthy. The right auricle was extremely distended, and there was a difference of opinion as to whether its walls, and those of the right ventricle, were not considerably thinner than usual. In texture the organ was somewhat softer than normal, tearing easily. No microscopic examination was made. The valves were normal.

This case is not unique in medical records, yet it is one of deep interest, and especially in regard to the action of anæsthetics. It is useless to speculate upon what might or might not have been done. I cannot, however, abstain from expressing one or two convictions. First, that under full anæsthesia this man would not have died at the time and in the manner that he did. Second, that with *partial* anæsthesia, his death would have occurred as it did, and gone to swell the list of casualties from anæsthetics. He evidently died from inhibition of the heart's action, the impulse being transmitted from the puncture. The mode of death was precisely similar to those which have occurred from tooth drawing under chloroform when movements of the patient, etc., were proof that the anæsthesia was not profound.

CASE OF INTESTINAL OBSTRUCTION IN AN INFANT CAUSED BY THE INGESTION OF WOOL.[1]

BY WM. R. WHITE, M.D.,
OF PROVIDENCE, R. I.

I WAS called at 1 A.M., February 12, 1884, to see E. H., a girl twelve months old, whom I had never seen previously. Her mother gave the following history: The baby had been vigorous and healthy in every respect from birth, and had developed rapidly, being able to walk unaided and to talk considerably. Her only nourishment had been breast-milk, except now and then a little bread or cracker. She had never had any intestinal trouble until now. There had been no evacuation of the bowels for the last two and a half days, and for the last twenty-four hours the child had been very restless and uncomfortable, not sleeping, refusing to nurse, and evincing abdominal pain. To relieve her, the mother had given no medicine whatever, but had tried several enemas of molasses and water, but with no avail. The last one, administered the evening previous, had caused a severe convulsion, which, however, was not of long duration. The urine had been voided naturally, and there had been no vomiting, but frequent retching and eructation. I first saw the child about five hours after the occurrence of the convulsion already referred to, and found her lying awake, but quiet, on the bed. She was not feverish, and evidently not in severe pain. The abdomen was slightly protuberant, but neither tympanitic, unduly tense, nodular, nor tender on palpation. There was no evidence of thoracic or cerebral trouble. When asked particularly if the child had swallowed any foreign substance or any unusual or indigestible matter of any kind, the mother gave a *confident reply in the negative*.

I offered no special diagnosis, but from the appearance of the patient and the history of the case, ventured the opinion, that a prompt and thorough evacuation of the bowels would effect a cure. So far as could be ascertained, the enemas had been properly administered, and had not only failed to give relief, but had undoubtedly been the exciting cause of the convulsion, hence, it was thought best to discontinue that line of treatment.

I at once gave the child a powder containing two grains each of calomel and sugar, directing that the same dose be repeated in a few hours, if necessary. The effect of the single dose was, however, wholly satisfactory, as I was told, on visiting the case the next afternoon, that the little patient had seemed no worse during the remainder of the night, and that between 8.30 and 10 o'clock, A.M., there were four copious and painless dejections, composed partly of normal fecal matter, with which was mixed up a large proportion of *masses* of *wool fibres*, of which the quantity was so great as utterly to astound the mother. She at first did not recognize the nature of the foreign substance, but on detecting unmistakable pink and blue fibres among the rest, the case became clear to her mind at once, as she then remembered having often seen the baby picking at the fleece of the soft woollen blanket on its bed, and that she had more than once removed wads of these fibres from the child's mouth, but had no idea that any had been swallowed.

The dejections had been already disposed of in the water-closet, so the writer could only judge of the amount of wool they contained by the estimate of the mother, who affirmed it to be at least as much as she could hold in her two hands.

The baby was then running about the house, bright and well as usual, and there were no signs of intestinal trouble subsequently.

THE GALVANOCAUTERY IN THE TREATMENT OF PAPILLOMA OF THE LARYNX.[1]

BY ALEXANDER W. MACCOY, M.D.,
OF PHILADELPHIA.

SINCE the advent of cocaine, the field for the successful use of the galvanocautery has been immensely widened. While many other destructive agents used in intranasal and laryngeal surgery have had their scope enlarged by the discovery of the anæsthetic action of cocaine, the advantage has not been so marked for them, as they were already in general use while the use of the galvanocautery was limited.

It goes without argument that the galvanocautery had already become a most efficient agent in the cure of chronic inflammations of the nasal chambers, nasopharynx, and pharynx, before the discovery of the properties of cocaine. It is also well known that morbid action causing growths in the larynx which required destructive agents had been almost entirely treated with forceps, caustic, etc. So far as the literature shows, workers in laryngology, with a few exceptions, made use of every other means before the galvanocautery was tried—many "damning it

[1] Read before the Rhode Island Medical Society, December 16, 1886.

[1] Candidate's thesis for membership in the American Laryngological Association, session of 1886.

with faint praise," while others utterly condemned it. That it should have been condemned some years ago as a dangerous and cumbersome means of accomplishing the destruction of tissue in the larynx is not to be wondered at when we consider its lack of adaptability at that time. The galvanocautery has passed through an extraordinary evolutionary period since the diseases of the nasal passages have been studied under new light and pathology. What was, a few years ago, heavy, awkward, and unfit in construction—including battery, handles, and electrodes—for intranasal and laryngeal application, has now become delicate, adaptable, and light. This applies particularly to handles and electrodes. The battery, once uncertain and vexatious, requiring one or two assistants in its use, is to-day simple in construction, always ready, and requires no assistant—being worked by the foot of the operator. Contemporaneous with the latter part of this period of evolution came the drug necessary for fully and perfectly preparing the surfaces and making the contact of the incandescent point painless and precise. We are now, in my judgment, living in "times that are ripe," where all the conditions necessary for success in the use of the galvanocautery in the larynx are present.

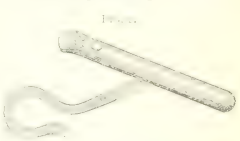
During the last few years, it has been my fortunate experience to have had under observation some cases of laryngeal papilloma, in which I could contrast the beneficial effects of a number of plans of treatment. At the beginning of the study of these cases, my bias was strong for the employment of the forceps, blunt and sharp. While these instruments were usually efficient in the removal of these growths, the well-known habit of their recurrence always made the treatment laborious and of long duration. Indeed, in several instances, their reproduction and tendency to spread were so active that nothing appeared gained after weeks of assiduous attention. With chromic acid I had indifferent success in getting rid of the *tendency* to spread or increase, until I used the laryngeal applicator devised by me.[1] But even this device is better adapted for the application to small sessile points and *small* growths in the anterior commissure of the vocal bands, etc., than to large, diffused masses, or cases where the growth is more defined, single or otherwise.

In the galvanocautery I had my greatest expectations realized, not only in the marvellously rapid disappearance of the papillomatous masses, but chiefly in the fact of the change of conduct of the tumors as to their persistent inclination to grow again. This point appears well established, while giving due consideration to the natural history of these growths in their ability to cease development and disappear after a certain time of growth or reproduction. While this fact appears clear to me, I am not of the opinion that the use of the galvanocautery applied with the usual knife, loop, or button would effect a more permanent result than some other agents, but that the result only becomes permanent when the electrode is so formed as to be able to penetrate to the heart or base of the mass, and there cause destruction to the nutritive and vascular supply of the papilloma. I have, therefore, employed a finely pointed electrode (Fig. 1), insulated well down the

FIG. 1.

point, and covered with some material impervious to moisture, and perfectly smooth. It is understood that the electrode is made of copper wire in the lightest manner, rendering it flexible and easily bent at any angle. With an electrode so constructed, I have found it possible to destroy growths very difficult of access with ordinary forceps, and, in some cases of subglottic growths springing from underneath the vocal bands, and seen only on deep inspiration, I have been enabled to destroy them completely by the use of this sharp-pointed electrode curved so as to reach the mass to be destroyed.

The hard-rubber handle generally used was found entirely too heavy for delicate work, either in the nasal chambers or larynx, and, after some experimenting—also utilizing what others had worked out—I made use of a very light handle, and Dr. Starr's improved connections (the binding posts placed in the middle of the handle instead of at the end, and the conducting cords made fast by a spring to the handle in such a manner as to allow the handle to work upon a hinge, as is well known).[1]



An instrument (Fig. 2) was thus formed which enabled me to apply the point in the most difficult places and in a very delicate manner. The Seiler-Flemming battery, single or double, with latest improvements, has proven invaluable to me. The activity of the battery should be at its greatest when the galvanocautery is to be used in the larynx. A perfectly *white* heat is necessary, and must be so quick in action as to render the surrounding tissue more safe from injury than would a dull red. An electrode at a "cherry red" has no more use in the larynx than in the nasal chambers. I have found the reaction very insignificant, and although I have applied an electrode point to a growth repeatedly at the same sitting, I have never had any acute œdema, great swelling, or much soreness following these applications. This is due chiefly to two conditions: first, the point is buried in the growth before the current is allowed to flow; and second, the action

well-known manufacturer of electrical batteries, etc., of this city, for galvanocautery use. The former handle weighed nearly three ounces, while this one is only three-quarters of an ounce.

at white heat is so rapid that the contact need be but for a few seconds at most, and no heat is distributed to surrounding tissue. Applied in this way, no surface is denuded, no wounds in contiguous tissue occur to form niduses for new growths.

The practical details of this method are, in my experience, few, but these few have to be carefully followed. Less than a twenty per cent. solution of cocaine has not proved satisfactory to me in getting complete anæsthesia of the larynx. With a twenty per cent. solution complete quietude is obtained. With renewals of this solution at intervals of from ten to twenty minutes, this condition can be maintained for at least one hour. After operating, the spasmodic action becomes more pronounced, and, when a certain time has elapsed, or a certain amount of interference has been tolerated, the irritability becomes so great as to preclude all further procedure at that sitting.

The external covering of the electrode must be smooth, or, in spite of the cocaine, spasmodic action will arise, as the shank passes over the free edge and under surface of the epiglottis. Until I worked out this problem for myself, I often failed to obtain proper access to the larynx, because of the spasm for which I could not fully account. It is, therefore, advisable to cover the silk insulating the copper wires with a thin rubber tube—a small drainage tube, or the rubber tissue used by dentists, or isinglass silk plaster, which is only impervious to moisture for a short time, but very well adapted to the purpose, and easily applied.

The effect of the galvanocautery upon a papilloma is to change it to a pale or whitish mass, rendering it even more friable than it is naturally; sometimes quite a considerable portion of the tumor comes away, adhering to the electrode. Aside from some additional redness, the interior of the larynx shows no abnormal state. After several days the destroyed mass has separated, and, if necessary, another application can be made; the soreness or pain following is insignificant.

The following case fairly illustrates the advantages claimed for galvanocautery over other treatments in papilloma of the larynx. During the early part of April, 1885, F. W., male, æt. twenty-eight, applied to me for relief for a loss of voice. His history is as follows: In May, 1883, he first noticed that he could not sing low notes (B flat); his voice was uncertain, and often failed him; he had not noticed any cold. He could not sing bass (his customary part), but could easily sing in tenor register. This condition continued during the summer. In September, 1883, he began to notice that his speaking voice was growing hoarse and getting weaker; had a short cough. Continued hoarse all winter. In April, 1884, he went to a medical clinic in this city, where he was examined, and an opinion given that he had paralysis of the left vocal band. He spent the summer of 1884 at the seashore, his voice constantly growing thinner and weaker. Lost flesh, but appetite continued good; tried electricity. During the winter of 1884–85 his voice still continued growing weaker; finally, a stoppage in his breathing occurred when asleep, awaking him with a start, and a long, stridulous inspiration followed. Any exertion was followed by obstructed and difficult breathing. This state of affairs continued until his voice was reduced to a whisper, and a feeling of suffocation was often experienced. In April, 1885, he came under my observation. Laryngoscopic examination showed at once the cause of all his difficulty. The appearance of the interior of the larynx is faithfully portrayed by Dr. J. Madison Taylor, in the accompanying pictures (Figs. 3 and 4). The left vocal band and

FIG. 3.

the arytenoid were seen to be immovable upon phonation, remaining abducted; paralysis of the lateral crico-arytenoid and arytenoid muscles; the right vocal band was only partly visible, being obstructed in its middle and anterior portion by an overlapping tumor of irregular outline, and of a pale red color. It was quite bulky, and appeared to spring from beneath the vocal band. On phonation, the growth in part appeared between the vocal bands, and prevented free movement of the right side. This tumor was first attacked with forceps, after a twenty per cent. solution of cocaine was applied. The larynx was unusually deep-seated, so to speak, and the ordinary right-angled forceps of Mackenzie were too short, only a small portion of the growth being torn

FIG. 4.

off. No more of the mass being obtainable by forceps of the usual length, forceps an inch longer were made. These were more efficient in reaching the growth, but what was gained in length was lost in power, and while a considerable portion of the tumor was removed, no perceptible gain was made, as the papilloma seemed to grow as fast as it was removed.

After many attempts to use forceps of other shapes, guillotine, and snares, I abandoned all these, and began treatment with the galvanocautery point. The tumor had now grown to greater dimensions than when first seen. The larynx being fully anæsthetized by cocaine, a pointed electrode covered with rubber was easily introduced, and the point pushed well into the papillomatous mass; connec-

tion was then made, and after a few seconds the point was withdrawn, showing the mass in part a whitish color. Considerable shrinkage took place in the tumor, and no unpleasant secondary complications whatever followed. These sittings were continued until the mass was reduced to a mere thickened outline underneath the vocal band; this was finally removed. Patient's condition began at once, and continued, to improve; his voice improved as the growth grew less, and changed from a deep hoarseness to its natural tone. To-day his voice is fully restored, but not quite pure; it would be perfect, if it were not for the paralysis of the left vocal band. The right vocal band is normal in color and perfect in outline, no loss of substance being noticed anywhere. In phonation the right side over-rides so much to the left that the immobility of the left is fairly compensated.

1417 WALNUT STREET.

HOSPITAL NOTES.

MATERNITY HOSPITAL OF PHILADELPHIA.

Service of DR. BARTON C. HIRST.

SUCCESSFUL DELIVERY BY THE FORCEPS OF A LARGE HEAD THROUGH A SMALL PELVIS.

K. S., primipara, æt. 19, was admitted to the Maternity Hospital in the month of September. The measurements of the pelvis, taken at that time, were as follows:

Distance between iliac spines	25¼ cm.
" " " crests	26 "
External conjugate diameter, Baudelocque's	18 "
Internal " " diagonal	10¾ "
True internal conjugate diameter (estimated)	8¼ "
Distance between trochanters	29 "

Labor began at 1 P. M., October 4th; at 5 A. M., October 6th, or forty hours after the os had begun to dilate, the woman was in great pain, and was much exhausted. A contraction-ring (the upper margin of lower uterine segment) was plainly visible not far below the umbilicus. An examination showed that the os was about three-quarters dilated, and that the child's head was pretty firmly fixed at the superior strait, in the second position (R. O. A.). The patient was anæsthetized, the forceps applied with some difficulty, and after almost two hours of vigorous but intermittent traction, the child was delivered, deeply asphyxiated; every known method was used for its resuscitation, and finally, at the end of thirty minutes, regular respiration was established. The child is at present (October 29) alive and well. The measurements of the head were as follows:

Occipito-frontal diameter . .	12¾ cm.
Occipito-mental " . .	14 "
Biparietal diameter	9¼ "
Circumference (occ.-front.) . .	36½ "

The bones of the skull were unusually firm and unyielding to pressure. With the exception of a rather extensive laceration of the cervix, the woman was uninjured, even the perineum being found intact; the puerperium was normal in every particular.

Remarks.—The fortunate termination of this labor, both for the mother and child, was rather extraordinary in view of the marked disproportion between the size of the head and that of the pelvis, and while the application of the forceps to the head before it had become completely engaged in the pelvis, and before the cervix was fully dilated, may be unfavorably criticised, yet it was justified by the imminent danger, not only of the formation of sloughs from the prolonged pressure of the child's head upon the maternal soft parts, but also of rupture of the uterus.

MEDICAL PROGRESS.

AN INVESTIGATION TO DETERMINE THE PROPRIETY OF OÖPHORECTOMY was undertaken nearly a year ago by the Liverpool Medical Institution, and its conclusions are of interest in view of the frequent performance of the operation in America.

The committee reported as follows:

"That the cases submitted to 'ovariotomy' were fit and proper, and that the operation was done successfully; that the operations for 'exploratory incision' were justifiable; that the operations for 'oöphorrhaphy or the replacement and fixation of prolapsed ovaries' were insufficient in number to enable the committee to form a strong opinion for or against the proceeding, but that the relief afforded by the operation was by no means clear and decided; that sufficient care and discrimination had not been exercised in the selection of cases for spaying, and that in many instances the gravity of the symptoms was not such as to have justified abdominal section of any kind; that in ordinary cases of pelvic hæmatocele spaying is not to be recommended; that the reports of the cases in which spaying was performed for 'bleeding myoma' 'signally fail in giving any description of the size and character of the myomata, or of the state of the uterus when the abdomen was opened at the time of the operation;' and that certain patients were reported as cured when the patients themselves stated that they still suffered from hemorrhage. The committee further finds that of ninety-two patients submitted to the operation of spaying, fifty-nine were between twenty and thirty years of age, and seven were only between seventeen and twenty years; that a considerable proportion of the subjects of it suffered a distinct loss of sexual feeling, and to such an extent as to cause serious domestic unhappiness in not a few instances; and that some of the patients complained of such a loss of physical energy and spirit as prevented them from discharging their ordinary household or other duties as they did before the operation. Many of the patients suffered from hernia in consequence of the operation. Many were distinctly and probably permanently benefited, while nearly an equal number experienced no decided and lasting benefit, while in some the operation proved injurious. The committee finally recommends that no patient should be spayed by any officer without consultation with a colleague, and that the patients should be clearly informed of the nature of the operation and its possible consequences; for the committee say that the patients examined by them very generally denied that sufficient information—or, indeed, any information at all—was given them respecting what was proposed to be done to them."—*The Lancet*, December 18, 1886.

TREATMENT OF PURULENT OPHTHALMIA OF THE NEWBORN.—DEHENNE divides these cases into two classes: simple ophthalmic catarrh and purulent ophthalmitis. The former the writer treats as follows:

Applications by camel's-hair pencil, once in two days, of solution of nitrate of silver, 1 to 100, which should be immediately followed by an application of saline solution; this should be done by the physician himself.

The daily use of a solution of atropia, five or six drops, in strength 1 to 400.

Lotions of cold camomile water.

Evacuation of pus and mucus by syringing with boric acid, 1 to 30, every three hours.

In purulent ophthalmia, the closest care of the child is needed night and day. The unremitting application of ice or ice-water is required, and pencilling with nitrate of silver solution, 1 in 40, twice daily, followed by the careful use of the saline.

Silver must not be dropped into the eye or used in the solid. If benefit follows the pencilling, it should be done once only in twenty-four hours.

Four times daily the following collyrium:

Eserinæ sulphat. neutral. . . .	gr. jss.
Aquæ destill.	℥vij.

When perforation of the cornea has occurred, eserine limits necrosis and gives a better field for subsequently forming an artificial pupil.

The eye should be syringed with solution of boric acid, 1 to 20, hourly.

After the secretions have been removed, a very small amount of a mixture of bichloride of mercury and vaseline, 1 to 3000, should be placed between the lids.

Collyria containing metallic salts should not be used. —*L' Union Médicale*, December 2, 1886.

TUMORS OF THE BLADDER.—At the last meeting of the London Clinical Society SIR HENRY THOMPSON contributed a paper on tumors of the bladder, in which he gave a brief sketch of six cases in which he operated during the last twelve months, showing the parts removed in each case. In three the suprapubic operation was employed; in two the perineal incision only; and in one, that of a female, urethral dilatation was sufficient for the purpose. It may be added here that in two cases the result is without doubt a complete and permanent cure. In two others the disease, although known to be considerable, was more so than might have been expected from the preliminary examination, and death, in each case imminent, was in one certainly, perhaps in both, postponed for a short time. In each the operation was undertaken only with the view of palliating the patient's condition, not of saving him; removal of the growth, so far as this was possible, being the only mode of arresting severe and continuous hemorrhage. The remaining two cases are of recent date, and it is only possible to say that the patients have thus far progressed satisfactorily.—*The Lancet*, Dec. 4, 1886.

TREATMENT OF DIABETES MELLITUS.—In a communication to the *Practitioner* of December, 1886, DR. ROBERT SAUNDBY gives the results of his experience in the treatment of this disease.

His diet list includes meat soup, beef-tea, fish of all kinds, butcher's meat, poultry, game, cheese, green vegetables, gluten bread, custard, jelly, blanc mange, tea and coffee; eggs, milk, cream, macaroni, vermicelli, wines and liquors must be taken with strict moderation.

A small amount of fat is allowed, and cod-liver oil benefits some patients. As a substitute for sugar saccharin is used, and occasionally glycerine.

Mildly alkaline waters, with or without lemon-juice, and distilled waters, are drunk. Opium, the writer considers the most valuable drug known in the treatment of diabetes.

In coma copious alkaline enemata and strychnia hypodermatically given are the only means of treatment indicated, and the author has seen very limited success in their employment.

A PRESCRIPTION FOR MIGRAINE.—The following is the formula of DUJARDIN-BEAUMETZ:

R.—Ethoxycaffeine	gr. xij.
Sodii salicylat.	gr. xv.
Aquæ dest.	℥ jss.—M.

Sig. Dose from five drops to teaspoonful as indicated.—*Les Nouveaux Remèdes*, December 8, 1886.

POMEGRANATE ROOT IN INTESTINAL AFFECTIONS.—MR. EDWARD NICHOLSON, in a paper read before the Liverpool Medical Institution, calls attention to some little-known properties of pomegranate root. His experience with it has been mostly with young children in India. He found that whenever a young child lost its appetite, had more or less irregular bowels and a somewhat tumid belly, was peevish by day and restless at night, when it was wasting, and the symptoms were negative as to worms or fevers, decoction of pomegranate root invariably effected a cure. The symptoms were mostly found in children about two years of age, but might occur at any time up to seven years. No particular dietary was found necessary. He has since found the drug equally efficacious in similar conditions in children in England. He has usually given the decoction in ounce doses, three times a day, and has never seen any toxic effects from its use. In certain obscure diseases in adults, where there was cachexia with evidence of abdominal disturbance, he has also found the pomegranate root serviceable.—*Practitioner*, November, 1886.

THE PATHOLOGY OF ADDISON'S DISEASE.—RIEHL agrees with Nothnagel in the belief that the pigment which characterizes this disease is not contained in the *rete mucosum* as an integral part, but that it is found in wandering cells which convey pigment from the blood. These cells the author found in extravasated blood which escaped through diseased bloodvessels, often in thrombi. Masses of red blood-corpuscles were observed near the pigment cells.

Disease of the bloodvessels is the primary lesion, the coloring matter of the extravasated blood is absorbed by wandering cells and those of the *rete*, while a portion of the pigment enters the lymphatics.—*Centralblatt für die medicinischen Wissenschaften*, Nov. 27, 1886.

TREATMENT OF MARSH FEVERS BY ARSENIATE OF SODA.—DR. ROCHARD observes that since the expedi-

tions of the French to Tonquin, Madagascar, Senegal, and Panama, there have been a great number of obstinate cases of marsh fever and malarial cachexia met with in France, especially in Paris. Quinine in large doses had been found to make very little impression upon them. Arseniate of soda, in doses of one milligramme (= $\frac{1}{70}$ gr. Eng.) after food, with hydropathic treatment, exercised beneficial control. If the attacks were regularly periodical, the dose was administered eight or ten hours previous to the access.—*The Provincial Medical Journal*, December 1, 1886.

A New Local Anæsthetic.—Drumine is the title of a new Australian local anæsthetic discovered and described by Dr. John Reid, of Port Germein, South Australia. Euphorbia Drummondii is the species from the milky juice of which the alkaloid drumine was prepared. Cocaine is known to have a mixed action on sensory and motor nerves, and causes preliminary excitement; whilst drumine is said to have an almost purely sensory paralyzing effect, and does not cause excitement. Experiments were made on cats, and on the observer's tongue. It was injected into the legs of the former animals, and caused general dulness, with marked impairment apparently of all forms of sensibility. Placed on the tongue, nostrils, and hand of the observer, the resulting anæsthesia was most marked. The alkaloid has no action on the pupil, and small doses given internally produce no constitutional effect. It has been employed successfully in subcutaneous injections for sciatica and sprains. The experimentation has so far been imperfect and incomplete. We hope soon to have a fuller account of this new alkaloid, and to be able to give further information thereon. The amount injected subcutaneously was four minims of a four per cent. solution. Dr. Reid anticipates a brilliant future for the drug in the domain of nervous and cerebral diseases.—*The Lancet*, December 18, 1886.

Lanolin Mercurial Ointment.—The following is the formula of Liebreich:

Mercury	100 parts.
Lanolin	25 "
Mercurial ointment	5 "

Rub thoroughly together, and mix with 50 parts of mutton suet, to which, when melted, 175 parts of lanolin have been previously added. An elegant and smooth preparation results, without disagreeable odor.—*British Medical Journal*, December 11, 1886.

Aperient Wine.—The formula of Monin, as given in the *Progrès Médicale*, is as follows:

℞.—Tinct. calisayæ,
Tinct. simarubæ,
Tinct. gentian.,
Tinct. aurant. cortic. amar. . ää ℥ijss.
Tinct. ignatiæ . . . ℥ss.
Vini xerici . . q. s. ad Oij.

Mix and filter.

Dose, from one to two fluidounces.

Retention of Fœtal Membranes.—In the *Vratch*, No. 35, 1886, p. 625, Dr. Andrei R. Fischer, of St. Petersburg, states that he has met retention of more or less considerable portions of the chorion in forty-two out of 683 (or in 6.2 per cent.) cases of labor. Discussing the etiology of retention, he mentions that (*a*) the phenomena occur oftener when the third period of labor is managed after Ahfeld's method than when Credé's method is employed (7.4 per cent. against 5.7 per cent.); (*b*) in primiparæ the retention is observed twice as frequently as in pluriparæ (9.1 per cent. against 4.9 per cent.); (*c*) an important causal part belongs to chronic inflammatory processes developing in the fœtal membranes, such as endometritis decidualis and choriitis chronica [the author's opinion is well supported by 1, the fact that in twenty-nine out of forty-two cases of the retention, waters either passed too soon (ten cases), or were so slow to pass that it proved necessary to make a puncture (nineteen cases); meanwhile the latter means was required in only 23 per cent. of the remaining cases where no retention occurred; 2, by the fact that the retention occurs more often in premature labors (8.2 per cent.) than in labors at full term (5.7 per cent.)] Passing to treatment, Dr. Fisher observes that in all his forty-two cases of the retention he did not use any other prophylactic means except the administration of ten-grain doses of ergot. As a rule, the retained membranes came out spontaneously within four or six days after labor. In four cases (10 per cent.) hemorrhage occurred, which, however, depended not upon the retention, but upon preëxisting atony of the womb, or decidual endometritis. In twenty of forty-two cases (47.6 per cent.) no fever was present, in twelve (28.6 per cent.) an isolated rise of the temperature was observed; and in only ten (24.8 per cent.) cases repeated febrile rises occurred. The respective figures for the normal (non-retention) cases which came under the author's observation during the same period were 58, 17.6, and 24.4 per cent. In thirty-two of forty-two retention cases, slight endometritis was observed; it disappeared under the use of ergot, quinine, and vaginal injections. Basing his views on the facts as sketched above, Dr. Fischer comes to the general proposition that retention of the fœtal membranes is relatively harmless, and cannot give any indication for any therapeutic interference.—*London Medical Record*, Dec. 15, 1886.

Beri-beri.—Cornelissen, a Dutch surgeon, and Sugenaya, a Japanese army physician, have reported as a Committee appointed to investigate this disease.

They find it an infectious disease and contagious through the medium of bacilli. These bacilli resemble those of milzbrand, are somewhat smaller, colored by fuchsin or gentian-violet, and are visible when magnified 560 times. They are found in blood, lungs, heart, muscle, brain, spinal cord, and nerves of those who have died; they are capable of culture by Koch's methods.

The bacilli flourish both within and without the body, they may infect a room, and wooden houses are thought to be especially dangerous as affording a lodgement for them.

Immediate contagion from person to person has not been as yet observed; it is thought they gain access through the respiratory organs; improper diet is a predisposing cause of infection, while the possibility that drinking water may convey the germs of the disease is not yet determined.

Particular localities may be extensively infected; in Atjek barracks, buildings of all kinds, and vessels were dangerous.—*Deutsche medicinische Wochenschrift*, December 9, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 1, 1887.

RESECTION OF THE ANKLE-JOINT.

OPERATIONS upon the various joints have been much improved since the establishment of aseptic methods in surgery, and none has been more benefited than that of resection of the ankle-joint. The difficulties in the way of obtaining good results in this operation are now chiefly mechanical, and depend largely upon the difficulty of obtaining a free exposure of the parts composing the joint.

A great variety of methods of opening the ankle-joint have been proposed, one of the best of them being that of Vogt. This consists in making a longitudinal incision on the outer side of the extensor tendons, retracting these tendons strongly inward, dividing the extensor brevis digitorum, splitting the joint capsule, clearing the head and neck of the astragalus, and dividing the astragalo-scaphoid ligament. After this is done, a transverse incision is carried backward from a point just below the middle of the first incision and below the external malleolus, sparing the peroneal tendons, but dividing everything else down to the astragalus. The foot is then twisted outward, the anterior ligaments are cut away from the malleolus, and the interosseous ligament is divided. The head of the astragalus is then drawn outward, and the deep portion of the internal lateral ligament is divided between the malleolus and the astragalus, and, finally, the latter is drawn into the incision, and its posterior attachments severed.

It will be observed that everything is done to spare the tendons in this operation. On the other hand, Reverdin, of Geneva, has proposed a method in which a free exposure of the joint is obtained at the expense of a number of tendons. In this method an incision is begun at the inner margin of the tendo Achillis, carried horizontally across it, behind the ankle, to the edge of the extensor tendons at the upper border of the calcaneum. By a second incision the tendo Achillis and the peroneal tendons are divided, and afterward the ligaments of the joint. Reverdin did this operation successfully upon a woman who had ankylosis of the ankle-joint and resulting pes equinus, following fungous arthritis. His success in this case may have been partly due to the fact that division of the tendo Achillis might be expected to favor a cure of the talipes equinus. At the same time, such a division might, when the foot was not already too much extended—understanding this word in the popular sense—result in the production of a pes calcaneus, which would be manifestly disadvantageous. At the same time the division of the peroneal tendons might lead to inward displacement of the foot.

A better method than either of these has been employed by KOCHER since October, 1883, and is fully described, with five illustrative cases—four operated by Kocher, and one by himself—by DUMONT, in the *Archiv für klinische Chirurgie*, Bd. xxxiv. Heft 2, 1886. In this operation the foot is held at right angles to the leg, and an incision is made from the outer edge of the tendo Achillis, curving round and over the point of the external malleolus to the edge of the extensor tendons. The peroneal tendons are now exposed, and each one caught at two points by a ligature and divided between them. The astragalo-crural joint is now opened, the attachments of the ligaments of the astragalus and calcaneum, and the capsular ligament on the anterior and posterior edges of the tibia divided, and the foot is dislocated inward—care being taken not to break off the internal malleolus by using too much force. In this way the whole of the joint is exposed. The diseased tissue is now removed, after which the foot is replaced at right angles to the leg, and the divided tendons are united by sutures. This very important step of Kocher's method is carried out by means of an ingenious and peculiar form of suture. The ends of a suitable thread are passed by means of two needles into two points at the same level on the natural surface of one end of the divided tendon, and brought out at corresponding points on its cut surface, leaving a loop over a portion of the tendon above. The needles are then introduced into the cut surface of the other end of the divided tendon, and brought out at corresponding points upon its natural surface, drawn firm, and tied. This form of suture is less liable to give way than any other which we have seen proposed. The subsequent treatment of Kocher's operation is what is usual in a resection of the ankle-joint.

In all of the five cases of Kocher's operation the result was admirable, as estimated after a lapse of from more than a year to more than two years. In his first case Kocher found it convenient to divide partially the tendo Achillis, in order to secure a freer exposure of the joint, but this does not seem to have been necessary in any of his subsequent operations. In his third case a recurrence of fungous synovitis took place six months after the operation, and led to a second opening of the joint, which was this time made by an incision on the inner side of the ankle, parallel to the tendo Achillis. This recurrence does not affect the question of the feasibility and utility of Kocher's method, the adoption of which we do not hesitate to recommend.

We have already, in THE MEDICAL NEWS of July 24, 1886, discussed the subject of the operative union of divided tendons, and it is now a common thing for surgeons to secure such union without difficulty; so it is interesting to note that Kocher has availed himself of this possibility in such a manner as to simplify very materially the operation of resection of the ankle-joint, herein furnishing a new illustration of the fact that it is sometimes better to pass directly over an obstacle, than to devise laborious ways of passing around it.

TESTAMENTARY CAPACITY IN ILLNESS.

THE validity of a will or any instrument executed during a fatal illness is occasionally the subject of judicial inquiry on the ground of resulting mental incompetency. If the testator was in a state of active delirium from disease or any other cause, or if in an unconscious or comatose condition with loss of the power of articulation and muscular control to a degree that no sign could be made, a question of competency would hardly be seriously entertained if indeed it should arise.

Excluding from consideration all cases that might be placed in one of these classes, about which there would be a general assent as to their incompetency, there is an intermediate mental state of partial delirium, incomplete consciousness, enfeeblement of mental and muscular power occurring during prolonged illness, or from shock, in which the validity of, and even responsibility for, acts may be called in question. Physicians in general practice have had occasion to observe that the recollection of all occurrences during even a mild attack of continued fever vanished on recovery, notwithstanding the fact that during the illness the patient may have conversed responsively and rationally, and seemed free from delirium. While the patient responds to questions perhaps correctly yet in monosyllables, he does not originate or lead in conversation, and indeed is incapable of doing so. Surgeons recognize a state of mental paralysis and inability to carry on mental operations which may follow shock from sudden and severe injury or hemorrhage. Extreme pain and debility may also impair the will-power so that intelligent assent is questionable or in absolute abeyance. Even the exercise or control of muscular movements necessary to affix a signature may be lacking, and only possible, as has actually happened, with the aid of the guiding hand of an attorney or a friend who may be near. Doubts have been expressed, and testimony actually taken in court in certain cases, as to whether the signature appended to a death-bed will was that of the testator, or of the lawyer who prepared the document and probably guided the feeble hand.

If it is the confirmed experience of the physician and surgeon in those cases of mild delirium and suspension of mental operations accompanying fever, of enfeeblement of the mind and will-power from chronic and painful disease, or of hebetude and mental paralysis following surgical shock, that the memory of transactions occurring in one of these states fades on recovery, or that a condition of partial and even complete unconsciousness exists. While we might not be warranted in urging that all documents executed in one of these conditions should by law be declared invalid, the least that can be said is that great doubts must be entertained of the existence of testamentary capacity. It may not be possible to determine it exactly if death supervenes, but inferences may be drawn from cases that recover of which the history can be obtained. In three recorded instances in which wills were made during a fatal fever attended at some period with delirium, the validity of the instrument was sustained although contested. Whether on recovery the acts would have been recalled and annulled could only be a matter of conjecture. In two cases in which recovery subsequently occurred, one repudiated the document as contrary to fixed intentions, and both failed to recall the acts performed, although regarded by witnesses to be in a proper and disposing state of mind at the time of execution.

It may be a principle of law that a will which does not exhibit *prima facie* evidence of mental derangement, and which is executed in the form prescribed by law, ought to be admitted to probate. Grave doubts, however, should exist and be expressed, as to the mental capacity of all those cases in which there is a reasonable inference that the will-power and other mental faculties are so enfeebled by disease or shock as to be incapable of originating or framing a purpose; in those cases in which a suggestion to execute a paper, at a time when death is imminent, originates with friends who surround the death-bed, instead of in the mind of the sick person; or in which there is no evidence to show that the testator dictated the provisions of a will drawn in an emergency,

but which seem to have originated in the minds of those surrounding the dying man, who yielded perhaps a passive, parrot-like assent. Undoubtedly there are certain exceptional cases in which the preparation of a will, the details of which are clearly fixed in the mind, may have been deferred, and it may be possible to show that the mind, though impaired by disease, was still moving in the line of previously declared intentions.

Medical observation of the mental condition of the class to which reference has been made, as well as cases that have been reported, should be sufficient to induce extreme caution and reserve in forming opinions where a reasonable doubt of the capacity exists, whether the question is one affecting the validity of a will, a contract, or a release in settlement of a claim for damages, executed during the shock following railroad or other injuries. In such cases the weight of professional judgment and the presumption must be against the existence of testamentary capacity and the ability to make a valid contract.

POISONING AFTER INJECTIONS OF CORROSIVE SUBLIMATE.

Fleischmann, the first assistant in the obstetrical clinic at Prague, adds another to the already long list of deaths following the use of corrosive sublimate injections during and after labor. Two injections were given, one before and one after the examination of a young primipara; shortly after the second there was a discharge of bloody mucus from the vagina, followed by severe abdominal pain, a serous diarrhœa, and vomiting of a quantity of bile; on the following day labor was completed without difficulty, and as the symptoms of the day before were attributed to the absorption of a small quantity of the mercurial salt, carbolic acid injections were used during and after labor. The mischief, however, had already been done, for, after exhibiting symptoms that pointed indubitably to mercurial poisoning, the woman died on the sixth day. The post-mortem examination showed spongy and swollen gums, ulcers on the tongue and pharynx, superficial ulcers in the ascending colon, and a high grade of acute inflammation of the kidneys.

Dr. Fleischmann ends his communication in the *Centralblatt für Gynäkologie* with an impressive appeal to the profession to banish corrosive sublimate from obstetrical practice. Instead of denouncing in this sweeping manner a drug that has proved itself of inestimable value as a germicide in obstetrics, it would have been better to consider the subject a little more carefully. If the hand is thoroughly disinfected before making a vaginal examination, and the infection of the vagina by germs carried in upon the finger is thus made impossible, the disinfection of the vagina after every examination is entirely unnecessary. Injections, therefore, of disinfecting solutions before labor being useless and sometimes dangerous, should not, as a rule, be employed. After labor, however, as the vagina may contain blood-clots, shreds of membrane, or meconium, and as its disinfection is desirable, it is justifiable to give one injection of a substance that can be depended upon to destroy all infecting germs that may have been deposited in these foreign matters, and in a situation most favorable to their growth and propagation; for this purpose nothing is better than corrosive sublimate, in a solution that need not be stronger than 1 : 4000.

The method of giving vaginal injections in Prague is presumably by means of a douche from a fountain syringe, as is the custom throughout Germany, and a very good method it is; but we are not told whether the vaginal tube, although perforated on all sides, is closed at the end, a seemingly trivial precaution, yet one that would, in all probability, have prevented the death in question, for the absorption of the poison was evidently due to the fact that the solution, entering forcibly the cervical canal, had separated to some extent the membranes from the uterine walls, thus allowing a poisonous dose of the drug to remain behind in the uterine cavity.

Used carefully, therefore, it is not likely that corrosive sublimate will meet with the execration of obstetricians, but that to it will be due the immunity of those who use it intelligently from that scourge of many practitioners, puerperal septicæmia.

HARVEY'S MANUSCRIPT NOTES.

The publication of these "Notes" under the supervision of a committee of the Royal College of Physicians of London, will be welcomed by every student of physiology, as they represent the original MSS. of the lectures delivered by Harvey in 1616, in which he set forth, for the first time, his discovery of the circulation. They antedate, by twelve years, the publication of his celebrated work *Exercitatio anatomica de motu cordis et sanguinis in animalibus*, published at Frankfort. He evidently pondered long upon his great discovery before the final announcement, and the notes are of great interest as showing how early in his work the demonstration had been made, and yet how careful he was to establish thoroughly and confirm his observations before sending them to the press.

As stated in the preface, these rough notes have a lesser value in illustrating Harvey's ways of thought and habits of observation. The text is interspersed with quotations and annotations, from which may be traced his anatomical reading and his acquirements in general literature.

In the early part of the notes, he lays down rules for the teaching of anatomy in lectures—*canones anatomicæ generalis*—from which we gather that he had a very clear conception of the duties of a teacher. He lays stress upon the following points: The importance of showing the relation of the structures by demonstrating, as far as possible, the whole of a part of a body at once; the necessity of illustrating the structure of man by that of animals, and bringing in points beyond mere anatomy, in relation to the causes of disease; to state things briefly and plainly; not to speak of anything which may be just as well learnt at home without the body, and not to spend too much time in minute details.

The manuscript is reproduced by the autotype process, with a transcript on the opposite page, and we must acknowledge the remarkable skill with which Mr. Scott, of the British Museum, has deciphered a handwriting which appears on many pages to be absolutely illegible. The work is published by Messrs. Churchill, and we are glad to learn that the number of subscribers to this splendid volume in this country is already considerable.

CHROMATE OF LEAD IN CAKES

By an interesting coincidence we present in this issue of The Medical News the detailed account of a very obscure case of lead poisoning, while related in a separate article, by an independent observer, there appears its probable explanation. Some years ago Dr. Hassal stated in the *Lancet*, that in England chromate of lead was used as an adulterant of Bath buns, and of egg and custard powders, a fact which suggests the possibility that in the poisoned cakes found by Dr. Marshall one of the commercial "egg-yolk" preparations may have been innocently used by some of the bakers. Wherever the blame may lie, however, authenticated cases of this sort are sufficiently rare in this country to excite the indignation of the community and demand action from the local health boards.

The final arrangements for the celebration next week of the Centennial Anniversary of the Institution of the College of Physicians of Philadelphia have been announced. On Monday, January 3d, a Commemorative Address will be delivered by the President of the College, Dr. S. Weir Mitchell, and will be followed by a Reception at the College. On Tuesday, January 4th, a commemorative meeting will be held at noon. Dr. Alfred Stillé will deliver an address entitled "Reminiscences of the College." The newly elected Associate Fellows will be introduced, and Dr. Da Costa will make a brief address of welcome. After the meeting luncheon will be served in the old Museum room. In the evening the Fellows of the College will dine together.

One of the features of the celebration will be a loan collection of portraits illustrating the early medical history of Philadelphia. This interesting and very valuable collection will be kept together until Thursday, January 6th, and may be viewed by visitors on presentation of the card of a Fellow.

At the election held this week for officers of the Philadelphia Hospital, Dr. John B. Deaver was elected surgeon; Dr. Roberts Bartholow, neurologist; and Dr. W. H. Wallace, physician-in-chief of the Insane Department.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 20, 1886.

The President, Charles A. Leale, M.D., in the Chair.

Dr. Frank Grauer read a paper on

THE PATHOLOGICAL ANATOMY OF SCARLATINAL NEPHRITIS.

Although a great deal has been done within the past ten years in elucidation of this subject, he said there still exist differences of opinion as to the minute changes that occur in the various forms of the trouble. The different forms of scarlatinal nephritis that are met with post-mortem may be classified, according to Friedländer, under the following three types: 1. The initial catarrhal nephritis. 2. The large, flabby, hemorrhagic kidney. 3. Acute glomero-nephritis, or nephritis post-scarlatinosa.

The first variety is met with during the first week of the disease, lasting a few days or a week, and then gradually disappearing. It rarely ends fatally, and is only recognized by a chemical and microscopical examination of the urine, showing a slight amount of albumen, mucous and hyaline casts, and, more rarely, red and white blood corpuscles, renal epithelium, and granular casts. In a majority of instances the kidney trouble is liable to be overlooked.

Post-mortem, the kidneys are found to be slightly enlarged and hyperæmic; the capsule strips off very readily; on a cut surface there is seen thickening of the cortical substance, with more or less loss of striæ, and the glomeruli appear as red clots. Microscopical examination shows swelling and granular degeneration, with desquamation of the epithelium, especially that lining the convoluted tubules. Hyaline and granular casts are often found in the straight tubes, and, where the process has been more severe, the beginning of a round-cell infiltration in the interstitial tissue. It is only in those cases in which children die from sequelæ or complications, such as diphtheria or bronchopneumonia, that we are able to notice the changes mentioned.

These changes would naturally be supposed to be those of a parenchymatous inflammation; but Friedländer, who had probably examined the largest number of cases microscopically, pointed out the following dif-

ferences: Parenchymatous inflammation, according to Virchow, leads to fatty degeneration of a cell, with disturbance of its function. This process does not occur in the epithelial cells lining the uriniferous tubules in this form of nephritis. Then, on the other hand, we have a cellular proliferation in initial catarrhal nephritis that, as a rule, does not occur in parenchymatous inflammation of the kidney.

The second form of nephritis, characterized by the large, flabby, hemorrhagic kidney, is not as frequently met with as the preceding or following form, and Friedländer found it present in only twelve cases out of the two hundred and twenty-nine that he examined. It probably occurred from the first to the fourth week of scarlatina, and ran a rapid course; the urine in some cases remaining normal up to within twenty-four or forty-eight hours of death, and œdema rarely occurring. It was generally found in those cases accompanied by extensive angina and diphtheritic inflammation. The kidneys were enlarged and softened. The cortical substance was thickened and grayish-red in color, and there was complete loss of the striæ, while the glomeruli, as a rule, were invisible. The cortex was studded with ecchymoses and large hemorrhagic infiltrations.

Microscopically, the tubules were found to contain the various forms of casts, red blood-corpuscles, degenerated and desquamated epithelium, and an increase in the connective tissue characterized by a round-cell infiltration situated mainly around the glomeruli and between the convoluted tubules. Small abscesses were often found in the cortical substance, in which, by means of one of the aniline dyes, micrococci could not infrequently be detected. Whether these micrococci had any distinct relation with the etiology of scarlatina or diphtheria, Dr. Grauer was unable to say. This form of nephritis is not characteristic of scarlatina, as it has been found in some forms of primary diphtheria; and Friedländer regarded it as a septic inflammation of the kidney.

Acute glomerulo-nephritis is almost characteristic of scarlatina. It rarely occurs in other diseases, though Dr. Grauer had met it once in a case of heart trouble. Klebs found it present only in scarlatina. It generally occurs in the third or fourth week of the disease, when the patient is convalescing. Probably without other symptoms, œdema is noticed about the eyes and lower extremities, and examination of the urine shows a high specific gravity and evidences of albuminuria. Microscopical examination shows hyaline casts, small epithelium, red blood-corpuscles, and, occasionally, epithelial and blood casts. In some cases the trouble is of short duration, but in others the œdema increases, fluid accumulates in the peritoneal, pleural, and pericardial cavities, while the urine keeps on diminishing in quantity and becomes more or less bloody. As the process goes on, we have uræmic symptoms with anuria and death. Friedländer found this form of nephritis present in forty-two cases out of two hundred and twenty-nine examined by him.

Klebs was the first to point out that the glomeruli were affected, and the results of his examinations are given as follows: In making fresh sections of the kidney with a double knife, he found that the glomeruli were anæmic, and on washing out the same in water they became dark and cloudy. By allowing the light to fall directly on the specimen they appeared as white points. Microscopically, he noticed small irregular nuclei embedded in a granular mass, within the capsule proliferation of the capsular epithelium, and the capillaries almost completely severed by a mass of nuclei. On tearing apart the glomeruli with needles, he found the glomerulo-epithelial cells more adherent than normal and varying in shape. Occasionally, some of the cells were found fatty. Situated between the glomerulo-epithelial cells and the walls of the capillaries were small irregular nuclei, and from their shape and appearance he came to the conclusion that they were nuclei of proliferated connective tissue cells, and that they produced a compression of the capillaries, which caused the diminution and suppression of the urine.

In this Dr. Grauer thought he was probably mistaken, as there was no evidence of connective tissue situated between the glomerulo-epithelium and the walls of the capsule in a normal kidney. Having discussed the microscopical anatomy of the glomeruli, he stated that Klein, in an examination of twenty-five cases where death resulted from scarlatina, observed the following changes: First, increase of nuclei, probably epithelial, covering the glomeruli; second, hyaline degeneration of the elastic intima of the minute arteries, especially the afferent arterioles. The intima of these vessels appeared in places swollen up into cylindrical or spindle-shaped hyaline masses, which produced a distinct narrowing of the lumen of the vessels. In connection with this, he observed a similar hyaline degeneration of the capillaries of the Malpighian corpuscles, in the course of which greater or smaller parts of the glomeruli became obliterated. The degenerated parts were at first hyaline; later on, they assumed a more fibrous aspect, Bowman's capsule at the same time becoming greatly thickened. A third change that he observed was multiplication of the nuclei of the muscular coats of minute arteries, and a corresponding increase in thickness in the walls of these vessels. The changes in the glandular part of the kidney were indications of a parenchymatous nephritis. He did not think that the anuria and uræmic poisoning were due to compression of the vessels of the glomeruli, but attributed them to the changed state of the arterioles.

Ribbert, from his examinations, came to the conclusion that glomerulo-nephritis consists in a swelling and desquamation of the glomeruli and capsular epithelium, with more or less accumulation of the same in the capsular space. The nucleated mass in the lumen of the capillaries he regarded as thrombosed white blood-corpuscles.

Having referred to the results obtained by Langham in the examination of twelve cases, Dr. Grauer went on to say that his own observations were based upon nine cases of glomerulo-nephritis which occurred at the Algemeines Stadisches Krankenhaus in Berlin, and were conducted at the pathological laboratory of Dr. Carl Friedländer. The results of the post-mortem examinations in the nine cases were then given in detail, after which he described the general microscopical appearance of the kidneys in glomerulo-nephritis as follows: They are enlarged and hyperæmic; there is no loss of cortical striæ, and in some cases the cortex may be somewhat thickened. The glomeruli are pale and prominent, and more or less enlarged.

As regards the microscopical appearances, he said, the uriniferous tubules are apparently normal. There may be some evidence of a slight parenchymatous inflammation; the epithelium may be somewhat swollen, and occasionally a cast may be seen in the tubules. The following changes were found in the glomeruli. They are bloodless, and a red blood-corpuscle is very rarely seen in the lumen of a capillary, especially when stained with hæmatoxylin and eosin. If present, they would be stained a rose color by the eosin. When examined with a low power the glomeruli are found larger than normal and covered with a mass of nuclei. With an immersion lens the following changes are noticed in the capillaries. In some the only change that is noticed is a thickening of the endothelial layer, which becomes more granular. In others the lumen of the vessel is filled with a rich nuclear protoplasm. The question that arises is, Are these nuclei the nuclei of the proliferated cells or do they belong to white blood-corpuscles, as described by Ribbert? Dr. Grauer's opinion is, that they are the nuclei of the proliferated endothelial cells, being smaller and darker than the nuclei of white blood-corpuscles. Again, he has seen an endothelial cell swollen and projecting into the lumen of the capillary like a cortical epithelial cell, and completely obliterating its calibre. In certain loops, he said, the lumen was filled with a reticulum, as described by Langham, in the meshes of which there might be red and white blood-corpuscles. The hyaline degeneration of the capillaries, as described by Klein, he observed in only two glomeruli.

With reference to the glomerulo-epithelium, he had noticed swelling and proliferation. The loops, however, as a rule, were larger than normal; showing that the pressure was from within, and not from without. Proliferation of the capsular epithelium, as described by Klebs, was not observed in eighty-two sections that he examined; although he observed it in other forms of scarlatinal nephritis. Hypertrophy of the left ventricle of the heart was always present in cases of glomerulo-nephritis, as first pointed out by Friedländer. It was due to the heart being compelled to do more work on account of the obstruction in the Malpighian tufts. In concluding, Dr. Grauer expressed the opinion that the term glomerulo-nephritis ought to be limited to those affections in which there is an obliteration of the loops of the capillaries, and not applied to those affections in which there is only a proliferation and desquamation of the glomerular and capsular epithelium, as this change has been noticed in all forms of chronic nephritis. A number of specimens illustrating the points brought out in the paper were exhibited under the microscope.

Dr. A. Flint spoke of the changes which had from time to time taken place in the views of physiologists in regard to the *rôle* played by the various parts of the minute anatomy of the kidneys in the excretion of urine, and stated that he had now returned to the opinion formed by Bowman from his researches in the structure of the Malpighian bodies and the vascular apparatus of the organ. Our knowledge of glomerulo-nephritis was of comparatively recent origin, and was chiefly due to the improved microscopes and the improved methods of staining.

One of the questions of interest suggested by the paper was in regard to death from so-called uræmic poisoning. This is a live question to-day, and personally he had very positive opinions in regard to it, which were considerably at variance with those formerly held by him. From the investigations which he had made during the last four years in regard to excrementitious substances, he had begun to doubt whether, after all, urea is a poison. His experiments had led him to believe that water was formed *de novo* in the system from the union of oxygen and hydrogen; so that under these circumstances it was an excrementitious product, and yet it was certainly not a poison. So there was good reason to suppose that carbonic acid was not a poison in itself. Some experiments made as long ago as 1840 showed that animals might be exposed to its effects indefinitely without any injury if the quantity of oxygen supplied to them was proportionately increased. It was the carbonic oxide, a deadly poison, which did the harm in cases where the fatal effect was usually attributed to carbonic acid.

As to the cause of death in those cases following scarlatinal nephritis in which it was commonly attributed to uræmic poisoning, he believed that those parenchymatous degenerations are due very largely to the excessive pyrexia of the scarlatina. The special direction which these parenchymatous degenerations take in different infectious fevers is governed, he thought, by the special cause of the disease; each affection having its own peculiar *contagium vivum*, with its specific mode of action in the system. In scarlatina there is a strong tendency for trouble to locate in the kidneys, and in scarlatinal nephritis the urine is diminished in quantity and concentrated, and contains a large quantity of albumen, because these organs become choked with excrementitious matter and can no longer be washed out by the water derived from the Malpighian tufts.

Dr. Isaac E. Taylor said that in the cases to which Dr. Grauer had directed special attention, death had occurred in from four to eight weeks. He should like to inquire what would be the result of an examination of the kidneys in those cases which sometimes occurred in which children were struck down in thirty-six hours. He related one case in which a child was suddenly seized with spasms, after which it became comatose, and died in a few hours. In another case, occurring in a family where scarlatina already existed, no eruption could be found except a slight blush upon one of the child's feet. In a few days, however, purpura hemorrhagica of an alarming character ensued; but recovery finally took place. He also related the case of two children in the same family. The eruption consisted in a slight blush upon the hands and feet, but in a few days anasarca set in, and death resulted.

Dr. L. J. MacNamara said that if there was swelling of the endothelial cell, filling up the calibre of the tubules, as described by Dr. Grauer, it would overthrow the theory formerly entertained that these tufts of capillaries are composed of nothing but epithelial cells, without nuclei. Or the condition noted might, perhaps, be explained by the existence of two sets of cells, one variety being nucleated and the other not nucleated. Again, it had occurred to him that if it were true that scarlatina has a special action upon the epithelial cells of Bowman's capsule, why did it not also have the same actions upon such serous structures in other parts, as, for instance, the

endocardium? It seemed to him that its action was on the endothelial cells.

DR. DANIEL BROWN expressed the opinion that the virus of scarlatina finds a soil particularly fitted to it in the skin, the intestines, and the lining membrane of the glands, and that by its effect upon these structures an irritation of the nervous system is set up that is sufficient to account for the class of cases to which Dr. Taylor had referred. It is very much as though the child died from shock. Scarlet fever has the effect of arresting almost all the secretions of the body; and, therefore, in his treatment he is in the habit of employing such remedies as tend to stimulate the secretions. By pursuing this course he has found that the temperature is kept down, and that the danger of unpleasant sequelæ is greatly diminished.

THE PRESIDENT said that some fifteen years ago, when attending physician for diseases of children at one of the largest dispensaries of the city, he was struck by the large number of cases of dropsy that presented themselves, and he found that the great majority of them were in children who had passed through attacks of scarlet fever without any medical attendance. Another important point was that in examining the urine, from day to day, in cases of scarlet fever, although for a time there might be no sign of kidney trouble, it was a fact that albumen appeared in it almost invariably on the twenty-first day. It thus followed close upon desquamation of the skin. When scarlatinal dropsy is moderate in amount, there is usually little difficulty in promptly relieving the patient.

DR. GRAUER said that in the cases referred to by Dr. Taylor, in which death occurred within twenty-four or forty-eight hours, there was complete suppression of urine, and that the condition found after death was acute glomerulo-nephritis.

PERFORATION OF THE APPENDIX VERMIFORMIS; LAPAROTOMY.

DR. JOSEPH D. BRYANT presented a vermiform appendix which he removed last summer. The case was one which he saw in a neighboring town in consultation with Drs. E. G. Janeway and W. T. Bull. The patient was a male, about forty-five years of age, with a good family history, and without any predisposition that could be justly claimed as the cause of his illness. About fifty hours before he was seen by Dr. Bryant, and without any appreciable exciting origin, he had been suddenly attacked with a moderately severe griping pain in the epigastric region. He had had a mild diarrhœa for ten or twelve hours previously, and, attributing it to this cause, he attached but little importance to it. Domestic remedies were administered, including a mild cathartic, which afforded him great relief.

About fifteen hours afterward the pain became more severe than at the outset, and was still confined to the epigastrium, there being no pain or tenderness whatever in the right iliac region. The family physician was now called in. He ordered a cathartic followed by an anodyne, but the former produced no characteristic effect. The pain increased in intensity, the abdomen became tympanitic, and nausea, with occasional vomiting, ensued. The vomited matter was not characteristic of any special morbid process. Enemata were administered which served to dislodge a few small scybalous masses only.

The condition of the patient became gradually worse, and Dr. Janeway was called in consultation about forty-five hours after the pain first commenced. About five hours later Drs. Bryant and Bull arrived, and at this time the following facts were noted: The patient's perceptions were intact, although blunted somewhat by the previous use of opium. Persistent, though not severe, nausea existed, with occasional vomiting, although the matter vomited still showed no distinctive characteristics. The abdominal walls were extremely distended, with tympanitic resonance well marked in all situations. Hepatic dulness was normal. Tenderness on percussion was general, but was best marked in the lower portions of the abdomen. No irritated point of special tenderness was discovered. All pain, however, was referred to the epigastric region, as at the outset of the attack. The abdominal walls were too tense to render deep palpation of any service as a diagnostic measure. Temperature 102°, pulse 108. The inspirations were increased in frequency, though painless; the increased frequency appearing to be largely due to the abdominal distention, The bowels were obstinately constipated, with an absence of all intestinal sounds and of appreciable vermicular movements. Digital rectal examination disclosed nothing abnormal. The thighs were flexed.

As the result of this examination, the consultants believed: (1) That a more or less general peritonitis existed; (2) that it was secondary to either obstruction of the intestinal tract or perforation of it; (3) that immediate measures of relief must be taken to insure a chance for recovery; (4) that medicinal measures afforded no such chance; (5) that an exploratory incision of the abdomen was warranted.

The patient having willingly consented to the operation, it was performed in as thoroughly an antiseptic manner as the circumstances of the case would admit. As soon as the peritoneum was incised a very small amount of thin, non-offensive, reddish-colored fluid escaped. The small intestine was extremely distended, and its serous surface was deeply congested. The sigmoid flexure (which extended across to the right iliac fossa) presented similar appearances. In some situations evidences of recent lymph were seen. No characteristic local indications of an obstruction could be found anywhere.

The intestines at and about the right iliac fossa presented the evidences of a more intensely inflamed condition, and for this reason the caput coli was closely examined. It, too, presented appearances similar to the contiguous intestines. The vermiform appendix was then brought forward, and with very considerable difficulty. It arose from the inner and peritoneal surface of the cæcum, was about two and a half inches in length, was covered entirely by peritoneum, and was unattached except at its origin from the cæcum. It was standing nearly erect between the intestinal folds. It was swollen and darkly congested, and presented somewhat the outline of a distended leech. At its base three perforations were found, two of which were each about the size of a small pea, while the other was of a smaller size. In one of the openings a small mass of soft fecal matter was located. At and around

the base of the appendix a considerable amount of the reddish fluid mentioned was seen, mixed with flakes of recent lymph.

The appendix was tied at its base below the points of perforation with a strong silk ligature, and removed with scissors. The toilet of the peritoneum was carefully performed with antiseptic sponges and a warm bichloride solution (1 : 10,000). A drainage tube was introduced, and the abdominal wound was closed and dressed antiseptically. During the operation the patient was stimulated frequently with hypodermatic injections of whiskey. At its termination the pulse was 120 and feeble. The patient could be roused to consciousness only with difficulty, owing, it was thought, to the opium which had been administered previously. He rallied, however, from the immediate effects of the operation, but died twelve hours after it from exhaustion.

Among the interesting features to which Dr. Bryant, in conclusion, called attention in connection with the case were the following: (1) The preceding diarrhœa; (2) the absence of distinctive pain at the seat of the lesion; (3) the location of this pain in the epigastrium; (4) the comparative quiet following the first attack; (5) the existence of normal hepatic dulness; (6) the extension of the sigmoid flexure to the right iliac fossa; (7) the unusual arrangement of the vermiform appendix; (8) the absence of the evidences of any restricting inflammatory process; (9) the uncertainty attending the diagnosis of the exciting cause of the patient's condition; (10) the unusual means adopted for the relief of the patient.

RHODE ISLAND MEDICAL SOCIETY.

Semi-annual Meeting held at Providence, December 18, 1889.

THE PRESIDENT, HORACE G. MILLER, M.D., IN THE CHAIR.

The preamble and resolutions for

THE PROTECTION OF THE MEDICAL PROFESSION,

introduced by Dr. F. C. Clark at the last quarterly meeting, were taken from the table, and, upon motion of Dr. C. H. Fisher, were adopted. They are as follows:

Whereas, The introduction by apothecaries of certain remedies has had an injurious effect upon the profession of medicine and tends to the usurpation of its functions.

Resolved, That the members of the profession use every means at hand to discountenance and discourage the employment in their prescriptions of any and every remedy put up and sold by any druggist, apothecary, chemist, or pharmacist, which compound comprises two or more medicinal substances, and has upon its label, or wrapper, or both, the ailment or ailments for which it is to be employed, with or without the dose, and appended thereto some name or title to attract attention to it, whether of physicians or others, and thus contributes to the injury and dishonor of the medical practitioner; and, furthermore,

Resolved, That all such remedies, with or without the name and character of their ingredients, be interpreted in the same manner and spirit as are those nostrums coming under Article I., Section, IV., page 37, of the Code of Medical Ethics,

DR. W. R. WHITE read a paper on a case of

INTESTINAL OBSTRUCTION IN AN INFANT CAUSED BY THE INGESTION OF WOOL.

(See page 7.)

DR. W. E. ANTHONY said he once saw a young child who was suffering from impaction of the rectum. On examination the finger encountered a hard foreign substance, which proved to be a squash seed. By using an ordinary button-hook, no instruments being at hand, *twenty-seven* such seeds were removed.

DR. R. F. NOYES mentioned the case of an infant, one year old, who had intestinal obstruction caused by swallowing an ordinary window-tassel, which was finally voided per rectum.

DR. F. C. CLARK approved of the use of calomel as a cathartic for young children. Of late he had to some extent employed the parvules of calomel—containing only one-twentieth of a grain each—giving five to seven of them at a dose. He had been surprised at the effects produced by what seemed to be so small a dose.

The Chair announced the following appointment of

DELEGATES TO OTHER STATE SOCIETIES:

Massachusetts, Drs. James H. Eldridge and H. R. Storer; Maine, Drs. F. B. Fuller, and C. V. Chapin; New Hampshire, Drs. Eugene Kingman and G. T. Swartz; New Jersey, Drs. T. H. Rankin and A. G. Browning; Connecticut, Drs. C. H. Fisher and F. T. Rogers; Vermont, Drs. C. H. Leonard and L. S. Hill; New York Medical Society, Drs. J. W. Mitchell and J. W. C. Ely; New York Medical Association, Drs. James H. Morgan and Charles O'Leary.

DR. E. T. CASEWELL exhibited a beautifully prepared specimen of a

DERMOID CYST OF THE OVARY

removed by him last June. The patient was single, fifty-one years old, and had known of the existence of the tumor for six months. An incision was made two and a half inches long, when the cyst readily presented. From the upper portion of the growth a considerable amount of pus was evacuated. The cyst was then found to contain a mass of dark brown hair and numerous small bones. Adhesions in front were difficult to break up, those posterior were easily broken. The patient made a tedious recovery, having to be nourished per rectum for some time on account of persistent vomiting. Later she had septicæmic symptoms and abscesses formed in the abdominal wall. In the end recovery was complete.

DR. CASWELL also reported a recent case of

OVARIOTOMY.

The woman was fifty-five years old. Fourteen years previous he had operated on her for the removal of a fibroid polypus of the uterus larger than a child's head. In the recent operation the incision was three inches long. The tumor with fluid contents weighed thirty-eight pounds. Full antiseptic measures were employed. Recovery was rapid and complete.

The Society then adjourned.

MEDICO-CHIRURGICAL SOCIETY OF MONTREAL.

Stated Meeting, December 3, 1886.

THE PRESIDENT, JAMES C. CAMERON, M.D., IN THE CHAIR.

DR. LAPTHORN SMITH presented a case of

PSORIASIS (?) FOLLOWING VACCINATION,

in a patient who was vaccinated during the epidemic of smallpox last year and the vaccine pock had not healed for six months; this eruption came out soon after the patient, who was previously a healthy young man, had been vaccinated.

DR. SHEPHERD did not think this was a case of psoriasis; it was a very good example of squamous eczema.

DR. T. WESLEY MILLS read a paper on the

CAUSATION OF THE HEART-BEAT AND OTHER PROBLEMS IN CARDIAC PHYSIOLOGY.

He remarked that in the light of our present knowledge some such statement of the case as follows may be provisionally accepted:

(1) The factors entering into the causation of the heart-beat of all vertebrates as yet examined are: (*a*) A tendency to spontaneous contraction of the muscle cells composing the heart. (*b*) Intracardiac pressure. (*c*) Condition of nutrition as determined directly by the blood, and indirectly by the nervous supply of the organ.

(2) The tendency to spontaneous contraction of muscle cells is most marked in the oldest parts of the heart ancestrally considered. He stated that he had shown (*Journal of Anatomy and Physiology*, vol. xxi.) that in the sea-turtle the last segments of the ventricle to pulsate are on its extreme right; while the right auricle outlasts the left, and the sinus and great veins beat much longer still. The same has been noticed in several other groups of animals. The most recently acquired parts of the heart are always the first to lose functional activity. These are but extensions of Harvey's observations, seen in the light of evolution.

(3) In all hearts examined intracardiac pressure is a factor of considerable importance; in some, as in that fish, menobranchus, etc., it is apparently the controlling factor. The same may be said of the molluscan heart.

(4) The power one contracting cell, when in action, seems to possess of initiating a similar state in others is of great significance.

(5) The influence of the nerves of the heart appears more and more as we ascend the animal scale. They seem only indirectly concerned in the causation of the beat by their influence over nutritive processes; but as the heart is being so frequently modified in its action, their influence in highly developed hearts becomes an almost constant factor, and of a degree of importance which our knowledge of the relation of nerve to muscle enables us, but inadequately, to appreciate, but which pathological changes ensuing on nerve section illustrate.

(6) It almost follows from the above that one part of the heart, having contracted, the other parts must follow. This is probably the explanation of the rapid onset of the ventricular after the auricular systole in the mammal. It will be remembered, too, that even in the mammal contraction begins in the great veins entering the heart. The basis of all these explanations is found in reality in the *natural contractility of protoplasm*. A heart in its most developed condition still retains (so to speak) the inherited, but modified, amœba-form in its every cell.

It seems likely to be shown that in the causation of the beat of the mammalian heart all the above mentioned factors enter.

In conclusion, he expressed his conviction that our present explanations of heart disease are of too mechanical a character; the nervous and the other factors indicated should more largely enter into the reckoning in the cardiac pathology of the immediate future.

DR. WYATT JOHNSTON presented a specimen of

EXTREME DILATATION OF HEART

on right side, obtained from a man, aged forty, who had died in the Montreal General Hospital. The right side of the heart contained twenty-seven ounces of blood and soft clot. Tricuspid orifice measured 9 lines in circumference, pulmonary orifice only slightly dilated, and valve competent; other valves normal; dilatation of the left ventricle very trifling; no hypertrophy of the heart-wall, and no marked degeneration of the muscle. Patient also had right-sided chronic tubercular pleurisy with dense fibrous exudation, and acute uniform miliary tuberculosis of both lungs in an extreme grade in connection with the arterioles. Dr. Johnston considered the case a puzzling one as to causation, as no caseating mass was discovered anywhere, and no connection of any such mass with the veins or thoracic duct. The adhesions could not embarrass the circulation in any way except by interfering with the contraction of the right auricle. He thought that the obstruction to the pulmonary circulation in the arterioles would have aggravated the dilatation of the right heart.

DR. GEORGE ROSS stated that the patient had been under his care in the General Hospital with symptoms of enormous pulsation of the epigastrium and right side of the thorax; the murmur was propagated to the hepatic region. The patient suffered greatly from cyanosis and breathlessness and died of inanition. He at one time thought that there was an aneurism of the abdominal aorta near where it pierces the diaphragm, but was much puzzled about the case and had not made a positive diagnosis.

PUERPERAL CERERRAL EMBOLISM.

DR. GEORGE ROSS showed a heart with warty vegetations on the mitral valves. The patient during life had been under his care, and had suffered from a right-sided hemiplegia with aphasia coming on even after confinement. The heart symptoms were those of mitral stenosis—presystolic thrill and murmur. At the post-mortem the left middle cerebral artery was found plugged with an embolus.

BIFID MECKEL'S DIVERTICULUM.

DR. WYATT JOHNSTON showed a Meckel's diverticulum almost three inches long which ended in a remarkable bifid extremity. He did not know whether it had any morphological significance but it was a condition he had never seen described and must be rare.

Dr. James Bell reported a case of

DILATATION OF THE STOMACH

caused by fibrous constriction of an inflammatory origin. The patient was a house painter and had frequently suffered from colic. The stomach symptoms followed a fall from a ladder in which several of his ribs were broken. Patient was under treatment for many months, had at one time vomited pus in large quantities, and had well-marked symptoms of dilated stomach. He had lost sight of patient till last week, when he heard he was under Dr. Lachapelle's care and suddenly developed symptoms of peritonitis of which he died in twenty hours. Dr. Lachapelle had kindly asked him to be present at the autopsy, when the following conditions were found. Fibrous constriction at the pylorus of an inflammatory origin, large abscess between the layers of the lesser omentum which had burst into the peritoneum and had caused fatal general peritonitis. The abscess communicated with the stomach through an ulcer at the pylorus. Dr. Bell attributed the whole trouble to the fall from a ladder eighteen months before and thought that if the patient had consented to operation his life would possibly have been saved.

TUBERCULOUS DISEASE OF BLADDER AND KIDNEY.

Dr. Bell also showed specimens from a boy, aged nineteen, with the following history. Some months before, he had entered the Hôtel Dieu for frequent and painful micturition, and one of the surgeons had performed a lateral cystotomy and removed, so patient said, a fleshy tumor; the wound never healed, and when he came under Dr. Bell's care at the General Hospital, in October last, the wound was still unhealed and all the urine passed by it. The boy had a phthisical appearance and soon developed symptoms of tuberculosis of the lungs. Tuberculous disease of the kidney was suspected, but satisfactory specimens of urine could never be obtained; the boy died of exhaustion ten days ago and the autopsy, performed by Dr. Johnston, showed old tubercular disease of the right kidney and ureter, the bladder was healthy, but prostate was extensively involved. The granulations in the wound were tubercular, and section through the wound showed tubercle bacilli in large number. The left kidney was healthy. The lungs showed acute tuberculosis. The patient had also very extensive degeneration of the synovial membrane and cartilages of the right knee-joint. During life the knee was perfectly normal in appearance, but he frequently complained of deep-seated pain in it.

A CASE OF LYMPHATIC LEUKÆMIA.

Dr. James Stewart showed a man, aged thirty-two, who was suffering from enlargement of the cervical, axillary, and inguinal glands. The following is the history of the case: The patient, a farmer, first noticed a swelling under his left lower jaw nine months ago. The glands along the sterno-mastoid and above the clavicles are very much enlarged, the swelling is painless and in some parts has a semifluctuating character. Glands in axilla size of hen's egg; glands in groin also much enlarged. The patient complains of weakness with palpitation and breathlessness on exertion. He is decidedly anæmic. Never had any previous illness; has lost three sisters from pulmonary consumption. No evidence of enlargement of the bronchial and mediastinal glands. Dr. Stewart thought the breathlessness might be accounted for by the anæmia and pressure exerted by the enlarged cervical glands and the trachea. Thyroid gland and tonsils not enlarged. No pain, tenderness, or swelling over any of the bones.

Dr. W. G. Johnston had examined the blood and reported that red corpuscles are well-formed, uniform in size, and nummulate normally. White corpuscles are considerably increased in number. There are also numerous small, colorless cells. By Gower's hæmocytometer, red cells 35,000 per c. cm.; white cells, 200,000 per c. cm.; proportion of white to red, 1–20.

On examining the spleen it is found considerably enlarged; its vertical dulness extending from the upper border of the ninth rib downward a distance of five inches; its surface is smooth. The liver is also somewhat enlarged. During last two or three weeks patient has been complaining of a dull aching pain over the lower part of back; no pain or œdema of lower limbs. Nothing abnormal in abdomen.

The case presented some difficulty in diagnosis. Its marked clinical feature was the hyperplasia of the superficial lymphatic glands. So marked was this enlargement that at first sight we would be inclined at once to come to the conclusion that it was a case of Hodgkin's disease. The very considerable increase in the number of white blood cells, together with the increase in size of both spleen and liver, made it more probable that the case was one of lymphatic leukæmia.

Dr. Stewart then stated that there are cases, and the one exhibited belongs to this class, where it takes some time to say whether we have to do with a lymphatic leukæmia or Hodgkin's disease, and asked if it were possible that a case of Hodgkin's disease may end in what we call lymphatic leukæmia.

Dr. Bell remarked that he had seen a number of cases of Hodgkin's disease whilst residing in the General Hospital and had followed some for a number of years without noticing much deterioration in the patient's health. He looked upon the case presented by Dr. Stewart as one of leukæmia because of the increased number of white blood-corpuscles. The prognosis of leukæmia is much more grave than that of Hodgkin's disease.

Dr. T. W. Wills said that the case was of interest because of the recent evidence that lymphatic glands are producers of red blood-corpuscles, and this case would support it from the pathological side.

NEW YORK NEUROLOGICAL SOCIETY.

[illegible] Meeting, December [illegible], 1885.

The President, C. L. Dana, M.D., in the Chair.

Dr. W. R. Birdsall presented the patient and read the history of

A CASE OF PROGRESSIVE MUSCULAR ATROPHY WITH BULBAR SYMPTOMS;

the atrophy limited to the left upper extremity, the abductor indicis of the right hand, and the tongue. The latter affected bilaterally (predominantly on the left side). He presented the case as illustrating the nonconformity of disease to our arbitrary standards of

classification and description of types of disease. The patient showed peculiarities due to the pathological process having advanced to an extreme degree in certain regions while its distribution had remained limited, not involving neighboring parts usually affected; the left upper extremity and tongue being the parts involved, and to a marked degree, while the right upper extremity was normal, excepting the abductor indicis; the trunk and lower extremities remained healthy. A detailed history of the case was given. The patient, a Swede, was a carpenter, aged thirty-nine years, married, of temperate habits, without a history of syphilis or other disease. A chart was presented showing the electrical reactions.

DR. E. C. SEGUIN had seen very few examples of unilateral progressive muscular atrophy. He had at present one patient under observation in whom the muscular atrophy was limited to one side, presenting the electrical and other characters of progressive muscular atrophy.

DR. W. M. LESZYNSKY had a girl aged seventeen years under observation in whom the atrophy was unilateral, affecting only the supraspinatus, deltoid, and a portion of the trapezius.

DR. E. C. SPITZKA read a paper on

SELF-ABUSE IN ITS RELATION TO INSANITY.

After citing the views of the classical writers, he stated that the question of the existence of a special form of insanity due to self-abuse and to nothing else, is complicated by the existence of another well-demarcated affection known as the insanity of pubescence. The mental diseases due to self-abuse usually occurred at the same period of life as the latter disorder. This fact explains the similarity of many clinical features between them. The question is further complicated by the fact that hebephreniacs (sufferers from pubescent insanity) are often addicted to self-abuse, and that thus the features of one disorder may be engrafted upon the other.

The continental authorities do not recognize a special form of masturbational insanity in their tables. Schüle, it is true, speaks of *onanistic insanity* in the sense in which Maudsley uses that term; but he assigns no part to it in his classification, and disposes of it in a few lines. Krafft-Ebing recognizes the vice as an etiological factor, and speaks of such and such forms of insanity on a masturbational basis. He, as well as Schüle, with the majority of recent German writers, follows Ellinger in attributing to the *masturbatory neurosis* a relation to the development of insanity analogous to heredity and other admitted predisposing and determining factors. I have yet to find any dissent expressed by these authorities from the position taken by Emminghaus, who claims that owing to its causal relationship to widely differing forms of insanity it is not proper to speak, as Skae does, of a special form due to masturbation. This critical remark would seem to be supported not only by the clinical facts accessible to every observer, but also by the confusion existing among those writers who have attempted to define and demarcate such an affection. Skae speaks of a peculiar imbecility and shy habits as characterizing the disorder among the youthful, and suspicion and fear, and scared looks, palpitation and feeble bodies as found in older victims, who gradually pass into dementia. The most distinguished follower of Skae attributes the following symptoms to that form of insanity of which masturbation is the chief cause and "the chief symptom present," giving "the whole case distinct features:" Exaggerated self-feeling, conceited shallow introspection, frothy emotional religious notions, and a restless, unsettled state with foolish hatchings of philanthropic schemes. Luther Bell who, with Isaac Ray, was among the earliest to attribute special symptoms to insanity caused by masturbation, furnishes a very faithful picture of certain cases, whose particular feature he describes as being a tendency to dementia, a loss of self-respect, a sulky, michievous, and dangerous disposition, and a subjectively irritable and depressed state of mind. Griesinger, who does not recognize a special form and denies specific characters, admits that the majority of cases are marked by a profound dulness of sentiment and mental exhaustion, by religious delusions and hallucinations of hearing, and a rapid transition to dementia in the event of incurability, which latter is the usual issue.

The effect of masturbation on the mind and nervous system varies according to the age at which it was commenced. Like other agents which are injurious to the developing brain, such as epilepsy, alcohol, and syphilis, its effect is most rapid and serious in younger children, less so in adolescents, and least marked in adults —unless protracted. For very young infants it causes a profound deterioration, manifesting itself in convulsive, choreic disorder, and imbecility. In those who masturbate between the fifth and tenth years, the effects seem to be manifested chiefly in arrested brain nutrition. Spontaneity of thought and action is absent with such children; they do not play as their comrades do.

There are a number of other circumstances which modify the development of mental disturbance in masturbation. The age between twenty and twenty-five is preëminently the period of somatic introspection. It is at this period, if at any, that the average man begins to think about his bodily condition. In these years men weigh themselves, discover that they have too much or to little flesh, develop slight gastric or intestinal disorders, reflex nervous symptoms, or indulge to excess in tobacco, in baccho, and in venere, and consequently are on the *qui vive* for the occurrence of cardiac, renal, or veneral disease, or of sexual disability. It is at this period that the results of masturbation are most deeply felt by a large proportion of the victims of that habit. The prevalent tendency of his age and of his associates of the same age carries him into a veritable nosomania. Perhaps also he attempts under lay or medical advice to accomplish coitus, and fails. It is for this reason that we find the larger portion of cases of insanity due to masturbation developing between the twenty-fifth and thirty-fifth year, classified as "hypochondriacal paranoia."

A number of typical histories were then related, from which the author drew the following conclusions: 1. Self-abuse is an etiological factor in a large number of cases of insanity, but only those cases should be designated as insanity of masturbation in which the connection between the excesses and the symptoms is direct. 2. Self-abuse, to produce insanity, must have been carried very far, or the subject must be predisposed. Often onanism can be traced in other members of the family,

[illegible] a weak one. 3. Mania, melancholia, and epilepsy occasionally occur in young masturbators, the former two usually having a favorable prognosis. 4. Stuporous insanity and katatonia are both common, and the former presents good prospects. 5. The forms thus far mentioned when occurring in masturbators present no essential difference from the typical psychoses. They should therefore be designated as mania, melancholia, stupor, etc., *from* masturbation, and not as masturbational insanity. 6. There is a chronic delusional insanity in grown persons who have been devotees of self-abuse, and it is usually a hypochondriacal *paranoïa*. Clinically it is very like typical paranoia, and etiologically it is not the direct result of self-abuse, but rather of an intermediate neurosis, a cerebro-spinal irritation which is due to self-abuse. 7. Finally, there is a form of insanity developing about or after the period of puberty which does merit the name "masturbational insanity." It is chronic, has a tendency to agitated dementia, is characterized in its early period by anxiety, timidity, suspicion, fear, and a cowardly, mean disposition. Later there are confusion, meddlesome, aggressive behavior, vague delusions, loss of memory, and finally deterioration. After these are observed spells of fury or destructiveness. This form is never due to any other cause, and resembles no other form of insanity than the one already alluded to. 8. It is not always possible to differentiate between the insanity of pubescence and the form described. But where the former disorder is uncomplicated by the latter, it may be known by a history of peculiarities in infancy and childhood, by the greater constancy of the mental state, which in onanists is exceedingly variable. Hebephreniacs are more apt to be expansive in their notions, more inclined to favor projects of a chimerical character. In other words, insanity of pubescence is the paranoia of adolescence, and masturbational insanity the presenile dementia of the same period of life.

Dr. Ralph L. Parsons thought that the diet should be principally vegetable and milk, with little meat and stimulating condiments. As the patient seeks solitude, he should be thrown as much as possible with others, not alone of his own sex, but also of the opposite sex. He should be kept occupied, and manual labor of some form, like farming, is best. He knew of no special benefit derived from medicinal treatment, as with the bromides, or the application of irritating substances to the penis. Cutting off the prepuce might be of advantage in some cases. The patient should be closely watched day and night. Mechanical appliances might sometimes be necessary; moral influence could be depended upon to a certain extent.

Dr. Kellogg agreed with the author in the conclusions arrived at in the main. But he would like to know Dr. Spitzka's views as to the relative importance of artificial sexual indulgence and indulgence in the natural manner as factors in the production of insanity. Masturbation is a wide term, and ought to be defined. The effects in some cases are more observable in spinal lesions, in others in cerebral lesions. He believed that masturbation itself is not capable of producing insanity in a person of sound heritage. He was convinced that it is capable of suspending mental growth and producing forms of imbecility in those of sound parentage. He knew it could produce insanity at the time of pubescence, and there were persons of mature age who had a predisposition to insanity, in whom the attack was excited directly by sexual excess. Occasionally persons indulged to excess for a year or two only, as did sailors sometimes when on long voyages. Masturbation is also capable of producing insanity in old persons who are on the decline; it hastens dementia. He did not think there is a peculiar set of symptoms; the age of the patient, his education, his heritage, his whole mental make-up influence the symptoms more than the exciting cause. He did not believe it possible to separate masturbation from other forms of sexual excess, and the title "sexual abuse" would have been more appropriate because more comprehensive than self-abuse.

Dr. Noyes said the case referred to by the author as having been cured, was the only one in the Bloomingdale Asylum in which a cure had been effected, and he attributed recovery in that case to transferring the patient to a farm, where his whole mode of life, including diet, was changed, and for the better.

Dr. L. C. Gray thought the author had given an accurate description of the mental disturbances often seen associated with the habit of masturbation, but he asked if he did not also find similar mental disturbances in individuals who were not masturbators.

Dr. Spitzka replied that in individual cases he had, but not in groups of cases as occurred in masturbators.

Dr. Gray had seen the mental disturbances described in patients addicted to masturbation, but he had been unable to decide to what extent masturbation could be considered as a cause or simply an associated habit. He had two cases in mind in which that group of symptoms were followed in the course of a few weeks by masturbation in individuals who had not previously been addicted to self-abuse. He had seen the same symptoms follow excessive sexual intercourse. He had in some cases noticed very exaggerated and extensive cremaster reflex.

Dr. Spitzka, in closing the discussion, said that there were undoubtedly some forms of sexual vice which were physically as injurious as onanism. But he had not seen a sufficient number of cases to enable him to say anything about their mental sequelæ unless he cared to risk being premature. He had known epilepsy and stupor to follow natural sexual excess in a young person, and paretic dementia in more than one cunnilinguist and sodomist. The form he had sketched is, so far as his experience goes, found only in masturbators. While he admitted with Dr. Kellogg that the single act of onanism is physically not a formal thing, and not much if anything different from normal coitus, there are two respects in which the onanist and libertine differ most widely: one is a moral, the other a physical, feature. The onanist practises a secret crime, the social and gregarious element is excluded. Knowing that his act is despised, he becomes inclined to suspicion and fear of discovery. A libertine cannot exceed beyond a certain limit. Coitus requires a certain condition of the organs which implies the existence of certain normal energies. When these fail the limit is set to further excess. With the onanist it is much different. There are masturbators who require no erection; who succeed in their injurious act even without any manipu-

lation. The consequence is that they pass far beyond the limit set by nature to natural excess, and no calculation can be made of the damage done. Dr. Parsons's dietary propositions were endorsed by the highest authority. Individually he was not decided in his own mind whether a highly nutritious diet would prove injurious in certain phases.

CORRESPONDENCE.

THOUGHT-READING.

THE wonder-seekers and lovers of the marvellous have recently been entertained in Boston and Philadelphia with Mr. Bishop's performances in "thought-reading." The audiences, receptively credulous, or critically skeptical according to the mental constitutions of the individuals composing them, have, at least, agreed in experiencing a bewildering wonderment over the exhibitions of Mr. Bishop's remarkable faculty. The psychological phenomena of the performances, and those developed in the audiences by these exhibitions of a mysterious power, must have some interest and value for physicians, and hence we present our readers with a brief analysis of the most salient points.

Mr. Bishop, who seeks to maintain before the public the attitude of a scientific investigator incapable of conscious imposture, entitles his performances "experiments." He ostentatiously divests his proceedings of any suspicion of deception by having his audience select a committee of the most reputable citizens to supervise all the details of the several tests. He also states with apparent candor—indeed, with an air of artless sincerity which is probably the perfection of art—that he, himself, is quite ignorant of the source and nature of his powers. He then requests all present to assume a mental attitude of unbiassed expectancy, and to postpone all discussion of the character of the experiments until they are concluded.

The act of "thought-reading," a term which Mr. Bishop prefers to "mind-reading," consists in the correct interpretation by him of some simple mental conception taken up for the purpose of the test by one of the gentlemen of his committee. To impart some picturesqueness and dramatic interest to the experiments, the thoughts are of such a character as stealing and hiding some object obtained from a person in the audience, stabbing some one and then concealing the dagger in an unexpected place, or writing on a blackboard the number of a bank note known only to those engaged in making the test, etc. Whatever may be the character of the test, the essence of it consists in a member of the committee taking up, and intensely fixing in his mind some particular act, which Mr. Bishop engages to reproduce in all its details.

Whilst he is being blindfolded in a neighboring apartment the act of stealing and hiding an object is done by some member of the committee designated for that purpose. To accomplish the reading of the thought Mr. Bishop must come in contact with the individual having it in his mind. In this the scientific attitude is supposed to be preserved, for, as is well known, an electric or nerve current cannot pass without an interposed conductor to transmit it. Before the actual contact is permitted to occur, Mr. Bishop performs, in sight of the audience, some passes and manipulations of the fingers which wear an aspect of mesmeric jugglery and detract from the scientific gravity of the experiment, although not without effect on the imagination of the spectators. The subject of the test trial is told to extend his hand, palm downward, and under it Mr. Bishop works his fingers rapidly for a few minutes; then striking an attitude, he suddenly places the back of the hand against his own forehead, and immediately assumes the expression of a trance-like state. Next placing the finger-tips of his left hand against the right hand of his subject, the pair start off hastily, Mr. Bishop leading on the search for the object hidden. The more rapidly he can lead his experimental subject the better; the more intently the subject and the audience follow the steps of the experiment the better; the more intense the sense of mystery and of occult power pervading the minds of all present the better—for thus all unconsciously contribute their aid to making the discovery.

It soon became evident that the band—a silk handkerchief accurately folded—did not cut off vision downward, and, hence, the ease with which he threaded the passages, and very effective the aid which his downlooking vision afforded in finding the person from whom the object hidden had been obtained.

What is the secret? Mr. Bishop alluded with a smiling disdain and no little derision to the various explanations that had been offered of his mysterious powers. Nevertheless, we submit our solution of the mystery. Mr. Bishop affirms that he can photograph (his own word) on his own mind, by the exercise of a peculiar attribute, the thought which dominates the mind of his experimental subject. Contact with his subject is necessary to produce, as contact is necessary to maintain, the impression. The absurdity of this claim must be apparent to any one acquainted with the simplest anatomical facts. The epidermis as effectually prevents actual contact of the nerve terminations of two persons touching, as a non-conductor does when interposed between the poles of the battery. The contact awakens the sense of touch, but separately and independently in each individual, and no passage of the nerve force across can take place for lack of the conducting bridge. Furthermore, Mr. Bishop's acts negative his assumption, for if the thought in another's mind is photographed on his brain, why does he rush hither and thither, often completely baffled for a time, in his search for the object hidden? He flies about in frantic haste, not to obtain the photographic impression, but to get his cue. How? By touch impulses, no doubt of a very subtile character, communicated by his subject; by the direction of the concentrated gaze of those in the vicinity of the person or hidden object, and the self-conscious air of the person from whom the object was obtained, both of which can be seen by him looking downward beneath the eye-band, when somewhat near.

The following considerations will render the above statements more conclusive. If the experimental subject possesses an acute wonder-sense, and is impressionable, especially if deeply interested in the experiment, he becomes more intent on Mr. Bishop's movements than of any movement made by himself. Under the same conditions, also, he becomes quite unconsciously a partisan of the performer, is gratified by success, and

equally chagrined by failure. This sympathetic appreciation influences the character and degree of the touch-impulses, and they are hence directive when the subject seems to himself to have maintained a merely passive attitude. The influence exerted upon the results of the trial-tests by the character of the subject, was admirably shown in one of the experiments made in Philadelphia. It was the second "experiment," and Mr. Bishop made a most unfortunate selection of a subject from the committee. He did not carefully observe, or his wits deserted him, or the devil who contrives to mix himself up with such matters blinded his judgment, for he designated a gentleman who by reason of his mental, moral, and physical attributes, is as little fitted as any man in the world to be the subject of such a trial. This gentleman, with the prominent brow, square and powerful jaw, and firm, unyielding mouth, with temperament to correspond, free from illusions, skeptical, if indifferent, was not one to resign his reason and judgment to the influence of a performer of mystical experiments. Hence he could communicate nothing, and being, as he said, "indifferent," Mr. Bishop received no guiding impulses, and ignominiously failed. Although before

> Whatever critic could inquire for,
> For every why he had a wherefore,

he now offered the lamest excuses, complained of the absence of the necessary sympathy on the part of the subject, and of the place where the articles had been hidden, which he maintained should have been in the sight of the audience. In the course of his explanations, he exhibited a good deal of chagrin, and was betrayed into more or less of the jargon used by the workers of spiritual "see-ants." It was subsequently observed that he declined the services of his immovable committeeman, but utilized those whose unconscious sympathy and impressionability had aided him before.

Sitting quite near the individual the subject of the stabbing experiment, the writer had an excellent opportunity to witness the demeanor of Mr. Bishop. When he approached, the victim had an unmistakably self-conscious air, which could be seen from beneath the eye-band looking downward. By this time Mr. Bishop had not only contact with his subject through his fingertips, but in the hurry and excitement he had drawn his arm within his own, apparently without consciousness. Fumbling in a hurried manner about the chest of the man supposed to be stabbed, and muttering "I must find the precise spot," Mr. Bishop could be seen to turn his head in such a position that glancing from beneath his eye-bandage he could catch the expression of his subject's face, who gave an evidently unconscious nod when the operator's finger rested on the spot where the dagger was supposed to have entered. Meanwhile, so intent were the subject and the audience on the experiment, so directive was the gaze of the audience, and the movements of the subject, that Mr. Bishop, though a less expert operator of the mystical machinery of the "see-ants," could have little difficulty in arriving at the dominating thought of his subject.

Mr. Bishop's faculty is the product partly of his temperament and original type of nervous system, and partly of acquired dexterity. He is thin, has auburn hair, and is a combination of the nervous and sanguine temperaments. He possesses by nature, no doubt, a highly sensitive apparatus for the reception of impressions, especially the tactile, and long familiarity and practice with all the machinery employed by the professors of the art of mysticism, have developed to the highest extent his original gifts. Before entering on the business of "thought-reading," he had become celebrated as a "Professor of the Art of Exposing Professional Humbugs of the Spiritistic Kind." Performing in this line, he has demonstrated the mode of conducting the most difficult tricks of the spiritual "See-ants." He unearthed the mystery of "Katy King" some years ago in Philadelphia. Thus gifted and accoutred, his touch developed to the utmost nicety of perception, and the other senses trained into the most accurate performance of which they are capable, and having an inherent aptitude for the working of such public entertainments, Mr. Bishop has an admirable equipment for his "line of life." The public, fond of illusions, amiably participate in the business of "thought-reading," and Mr. Bishop quite satisfies their critical faculty when he appears attired in correct evening costume, decorated with glittering orders, and just from audiences of empresses and princesses, himself the Prince of Mystery.

INTUBATION OF THE LARYNX.

As an earnest advocate of intubation, I would take exception to an editorial on "Intubation of the Larynx and Trachea in Croup," appearing in THE MEDICAL NEWS of December 4th.

Speaking of the danger of crowding membrane down below the tube when it is introduced, the writer says: "Should such plugging with membrane accompany intubation, and relief to respiration fail to follow the removal of the tube, immediate tracheotomy would be requisite, with far less hope of success than if it had been done in the first instance;" and again, "With intubation no attempt can be made to remove false membrane." In a paper read before the Chicago Medical Society, and published in the *Chicago Medical Journal and Examiner*, vol. liii., No. 2, it was my pleasure to exhibit a trachea forceps devised for this particular purpose. Reference to a single case will be sufficient to show the value of this instrument.

December 10th, I was called to see a child of seven years, by Dr. C. E. Caldwell, of this city. The patient was in the last stage of asphyxia from membranous croup. An intubation tube was quickly introduced, but the child was unable to breathe. There were several attempts at respiration, but no air entered the lungs. The tube, from absolute necessity, was removed. The respiration was carried on imperfectly, and the tube was again introduced, but with the same result as at first. The tube was withdrawn, and the long trachea forceps introduced by way of the mouth, and a perfect cast of the whole trachea, and of the two large bronchial tubes to the extent of one and a half inches, removed. The intubation tube was now introduced, and respiration was so quiet as to be scarcely observed.

Every one who performs intubation frequently should carry with him these forceps, for this is an accident that will occasionally occur.

The editorial concludes with the statement "That intubation will save many lives in cases in which tracheotomy would not be permitted; that it will save many a

patient from the need of tracheotomy; and that it will probably sacrifice a few lives which might have a better chance for preservation under tracheotomy." The first two conclusions are correct, but I would contend that intubation will save many lives that *could not be saved* by tracheotomy. I am forced to this conclusion by considering my record of cases under three years of age. We all know that tracheotomy is rarely successful under this age. Occasional cases are reported, but they are few and far between. It has been my pleasure to perform intubation somewhat over one hundred times, and with a success that can be attained only by a few with tracheotomy. Fifty-two of my cases have been three years of age or under, a great many of them nursing infants, with thirteen recoveries, or twenty-five per cent. Among those recovering, may be mentioned an infant of nine months, another of fourteen months, another of eighteen months, and another of twenty-two months. If any tracheotomist can show a better record with an equal number of cases at this age, we will then be convinced that intubation will not for the present supersede tracheotomy.

One of the chief objections to intubation is the difficulty of nourishing the patient. This difficulty will soon be overcome, and Dr. O'Dwyer's invention will then prove a boon to suffering children that cannot be overestimated. To overcome this difficulty, I have had tubes connected with very small heads, and use a rubber collar with an artificial epiglottis attached. The rubber collar projects sufficiently to prevent the tube slipping into the trachea, and, being elastic, fits more perfectly into the larynx than the large metallic head. When the child swallows the epiglottis presses the artificial epiglottis down, so as completely to cover the aperture of the tube.

W. E. WAXHAM, M.D.,
Professor of Diseases of Children,
College of Physicians and Surgeons, Chicago.

CHICAGO, December 21, 1886.

NEWS ITEMS.

THE PROPOSED LABORATORY OF PRACTICAL HYGIENE IN THE UNIVERSITY OF MICHIGAN.—At a meeting of the Board of Regents of the University of Michigan, December 7th, Drs. Lyster, Baker, and Vaughn, of the State Board of Health, appeared, to speak in favor of the establishment of a laboratory of practical hygiene in the University in accordance with the resolution of the State Board of Health given in THE MEDICAL NEWS of November 20th.

Dr. Lyster said: "It is time that the scientific men of America should be furnished with facilities for original research, and that they should no longer be compelled to wait for all such work to be done in Germany and France. The resources of our country are great, and it presents many peculiar sanitary problems which demand solution. In nearly every department of science and art, the University of Michigan has taken the lead among the educational institutions west of the Alleghanies, now let it inaugurate a department of hygiene. Certainly, nothing could be of more importance to the people than a study of the laws of health. Drainage, sewerage, water-supply, the adulterations of food, and the study of methods for restricting contagious diseases are questions in which every community is directly interested, and the educational facilities of the State could not be better employed than in instructing its citizens in the art of the preservation of health and the prolongation of life."

Dr. Vaughan, after speaking at some length, presented the following proposed schedule of studies:

I. The Air.

A. Physical studies:

a. Observations on temperature, and studies of the influence of temperature on health; *b*. Determinations of air pressure and the effects of variations in air pressure upon diseases of heart and lungs; *c*. Determinations of air moisture, and the effects of climate as influenced by moisture; *d*. Determinations of ozone.

B. Chemical studies:

a. Analysis of air; *b*. Study of organic matter in the air; *c*. Microscopical studies of matter in the air.

II. The Soil.

A. Physical studies:

a. Determination of porosity; *b*. Determination of moisture; *c*. Determination of temperature.

B. Chemical Studies:

a. Determination of organic matter; *b*. Analysis of ground air; *c*. Analysis of ground water.

C. Microscopical studies of the soil.

III. Water.

a. Physical properties; *b*. Chemical analysis; *c*. Microscopical examination; *d*. Diseases due to impure water.

IV. Foods.

a. Nutritive value of foods; *b*. Economical value of foods; *c*. Study of individual foods; *d*. Ultimate analysis of foods; *e*. Detection of adulterations.

V. Clothing.

a. Determination of fibre, and the detection of adulterations in fibre; *b*. Determination of coloring matter and the detection of harmful colors.

VI. Habitations.

a. Sanitary locations; *b*. Sanitary properties of building material; *c*. Studies of air-space and ventilation; *d*. Study of temperature and methods of heating; *e*. Water supply; *f*. Disposal of waste.

VII. Contagious Diseases.

a. Study of the nature and history of contagious diseases; *b*. Study of germs; *c*. Methods of restricting contagious diseases; *d*. Vaccination; *e*. Disinfection and disinfectants.

VIII. Original Investigations.

Dr. Baker said that he wished to endorse the outline which had been presented by Dr. Vaughan, and to emphasize the necessity of laboratory work in teaching sanitary science. It was generally understood that for the successful teaching of chemistry laboratory work is essential, but he thought it is not so well understood, as it should be, that for successful teaching in sanitary science a well equipped laboratory is essential. He hoped the Regents would ask the legislature for means to establish the laboratory, not because it had been recommended by the State Board of Health; but because it is right, and will make the University more useful in promoting the welfare of the people. The University can do no nobler work. He assumed that no elaborate argument was needed to convince the Regents of the University that mental training in sanitary science is

worthy to rank higher than training in any other science or in art or literature. The question should not be, Why establish an effective system of training in sanitary science? It should be, Why has this not been done long ago? But mankind had to wait centuries until many universities and educational systems had grown old before the question was raised: "What knowledge is of most worth; what sort of mental training is of most benefit to mankind?" He supposed that all present had read Herbert Spencer's work on education which started with that inquiry, and which laid down a few propositions which seemed so true as to require no proof. One conclusion was, that knowledge is of most worth which tends directly to preserve life. Another is in effect, that next in value is knowledge which tends indirectly to preserve life. And compared with such knowledge and training, much that has been taught in schools and universities must be placed low in the scale of immediate and prospective usefulness.

The University is charged with the noble duty of training the minds of those who are to become the leaders of thought throughout this State and in the nation. The State cannot afford to have its leaders untrained in sanitary science, ignorant of that knowledge which is of most worth. He trusted that the Regents would do all in their power to establish the laboratory, and a system of instruction therein, and as rapidly as possible raise it to that high plane which sanitary science is entitled by reason of its great usefulness to mankind.

After consideration and listening to the needs of other laboratories, the Regents determined to ask the legislature for $75,000 with which to erect a building which shall furnish space for the laboratory of hygiene, and also supply more suitable accommodations for the already existing laboratories of physiology, physics, and microscopy.

GYMNASTICS IN FEMALE COLLEGES.—A recent presidental decree in France, says *Science*, regulates the instruction in gymnastics in the *lycées* and colleges for girls. The instruction must be given by female teachers, who must have received a certificate of aptitude from the proper authorities. Such teachers are to receive from 1200 to 2000 francs per year each, and may be required to teach sixteen hours a week. They must teach at least twelve hours a week.

MORBID SENSE OF RESPONSIBILITY.—People sometimes think that medical men are apt to look upon their patients as machines or as corpora vilia for their experiments. How very far this is the reverse of the truth is probably only known to medical men themselves. Indeed the sense of responsibility is sometimes exaggerated to an abnormal or morbid extent, as is shown by a very sad occurrence which, as we mentioned last week, has just taken place at St. Petersburg, resulting in the self-destruction of one of the most gifted and esteemed surgeons there, Dr. S. P. Kolomnin, Professor of Clinical Surgery in the Military Medical Academy. He had to perform an operation on the rectum of a woman, and for the purpose employed cocaine anæthesia; the patient died in a very few hours after the operation from cocaine poisoning; at least, that is what is considered to have been the cause of death, but no details have as yet been published. The sad result took such a hold on the mind of the unfortunate operator, that, though his colleagues did their best to reassure him, and to show him that the result should be ascribed to an accident such as most surgeons have occasionally met with, it was impossible to prevent him from considering himself the culpable agent in the woman's death. This so preyed upon his mind that he shot himself with a revolver on November 23d.

AN EARLY MICROBIST.—The *[illegible]* claims the first thought of the germ theory of disease for a Dr. Goiffon, who died at Lyons more than one hundred and fifty years ago. He believed, in 1721, that diseases like the plague could be caused only by minute insects or worms; too small to be seen, perhaps, but nevertheless really existing. He also believed that the conveyance of infection could be explained by their activity and propagation.

NOTES AND QUERIES.

[illegible]

Sir, I [illegible] taneous gangrene in a child not quite two years old, resulting, probably, from embolism. I had never seen a case of such disease at that tender age. I can find no case recorded. Nor, after extensive correspondence with eminent members of the profession, can I learn of anything of the kind. I removed the foot at the tarsus (Heys's amputation). If any reader of THE NEWS knows of a similar case, either personally or in any way, he is earnestly requested to communicate it. T. C. WALLACE, M.D.

[illegible]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 21 TO DECEMBER 27, 1886.

FORWOOD, W. H., *Major and Surgeon.*—Granted leave of absence for one month.—*S. O. 129, Department of Dakota*, Dec. 16, 1886.

[illegible] from Fort Concho to Fort Clark, Texas.—*S. O. 174, Department of Texas*, Dec. 16, 1886.

[illegible] Ordered from Fort Grant to Fort Apache.—*S. O. 136, Department of Arizona*, Dec. 16, 1886.

MASON, CHARLES F., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Huachuca to Fort McDowell.—*S. O. 136, Department of Arizona*, Dec. 16, 1886.

BANISTER, W. B., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Wingate to Fort Lowell.—*S. O. 136, Department of Arizona*, Dec. 16, 1886.

DIETZ, W. D., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Stanton to Fort Bayard.—*S. O. 136, Department of Arizona*, Dec. 16, 1886.

POLHEMUS, A. S., *First Lieutenant and Assistant Surgeon.*—Ordered for duty as Post Surgeon at Fort Gaston, Cal., relieving

H. I. RAYMOND, *First Lieutenant and Assistant Surgeon.*—Ordered for duty at Angel Island, Cal.—*S. O. 123, Department of California*, Dec. 13, 1886.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. L. SATURDAY, JANUARY 8, 1887. No. 2.

CENTENNIAL ANNIVERSARY OF THE INSTITUTION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

COMMEMORATIVE ADDRESS.

BY S. WEIR MITCHELL, M.D., LL.D.,

PRESIDENT OF THE COLLEGE.

Delivered January 3, 1887.

WE are met this evening to commemorate the hundredth birthday of the oldest medical society in America which is not a State organization. New Jersey and Massachusetts have State Societies of older date, which of necessity met rarely, and were chiefly meant to give unity, force, and discipline to a profession, the members of which were widely scattered over a thinly peopled country.

One hundred years ago the grave and kindly man whose portrait hangs above me at our meetings, met the Fellows of this ancient College as their first President.

In words which quaintly represent to-day my own feelings, John Redman expressed his sense of the honor then conferred upon him and of the responsibility created by such an audience; "for," said he, "when I look around me, I see so many gentlemen of character for learning, ingenuity, and integrity in the profession and practice of physick, and some whose talents have early called them forth into public notice, and offices of dignity in the medical line, and who have conducted therein for many years so much to their own reputation, and to the advancement and satisfaction of their pupils and of their fellow-citizens."

To understand the men over whom he presided, to comprehend the inheritance of examples they left us, to realize above all how peculiar have been the relations of the physician to the social and political existence of Philadelphia, it is necessary to look back through the century which preceded the foundation of this College.

The history of any profession in connection with the progress and growth of a new country is of the utmost interest, and of no profession is this more true than of ours. The bar, the army, the navy, and, in other lands, the church, have distinct natural relations to the government, but the physician has none, and in monarchial countries this fact has served to create for him annoying social limitations which are but too slowly fading as communities grow into intelligent disregard of feudal traditions. His position in any community is a fair test of its good sense. But in new lands, peopled by the self-selection of the fittest, by those who have the courage of enterprise, and the mental and moral outfit to win for it success, the physician is sure to take and keep the highest place, and to find open to him more easily than to others wealth, social place, and, if he desire it, the higher service of the State. Nowhere was this more true than in this city. In New England the clergy were for a long time dominant. In New York then, as now, commercial success was the surest road to social position. South of it was the landholder, who ruled with undisputed sway. But in this city—I may say in this State—from the first settlement until to-day the physician has held an almost unquestioned and somewhat curious preëminence. He is and always has been relatively a more broadly important personage here than elsewhere.

If this be not as clear to you as it is to me, let me remind you that in every legislature of this Commonwealth you will find a dozen members of our profession who have for a time taken up the duties of law-givers, intending to return again to their practice. I observe on the list of our Fellows to-day many men—and they are of our best—who have been or who are directors of insurance companies or saving funds, or even of banks, a thing almost unheard of in cities where the lower civilization of commerce is dominant. You will find them, also, in unusual numbers on our collegiate boards. Our great charities are never without some of them in their councils; and the Philadelphia Library is obliged, under the will of James Rush, to have in its direction three physicians. In our hospital boards, and still more largely in our learned societies, they are equally well represented.

Says a learned historian, writing of the Philadelphia of 1828, "Nothing struck me so much as the social force and influence of the physicians. I was familiar with other cities, and nowhere else did they seem to me to be so distinctly the leaders of social life."

The exceptional position which we occupy here is in a large measure due to the good fortune which, early in our history, directed to these shores a remarkable group of physicians, the friends and co-religionists of Penn.

As I am chiefly addressing Pennsylvanians, I shall not venture to say much of men whose names are still familiar. I desire, however, to show what breadth of liberty they had to do things which nowadays would scarcely be regarded as within the legitimate career of the largest-minded physician. Edward Jones, chirurgeon, came over in 1682. His father-in-law, Thomas Wynne, set sail in the "Welcome," with his friend William Penn, in that same August. These were both physicians of gentle breeding and of the best education

their day could offer. Thomas Wynne was an active practitioner of physic, and yet found time to become President of the first Assembly which met in the province, and in which sat also his son-in-law, Jones. Both of these men lived to hold many offices of political trust and honor in their adopted country.

Next in our medical genealogy comes Thomas Lloyd. There is, what was called in Friend's phraseology, a testimony concerning him which, heard pleasantly across the turmoil of nearly two centuries, tells how that "he had a great practice, ... and generally good success, whereby it was often his lot to be amongst many of account in the world. . . . . Yet being a man of tender spirit, he was conscientously careful over his patients whether poor or rich."

In the new land he sought for conscience' sake he was still for a while a physician. How, think you, did he find time to act as Deputy-Governor under Penn, President of Council, Keeper of the Great Seal of the Commonwealth? Apparently the good and great William Penn took care of his physician, for we hear that his friend Dr. Griffith Owen held the posts of Member of Assembly, Deputy-Master of the Rolls, and Commissioner of Property.

The early part of the next century was as fortunate. Lloyd Zachary, the grandson of that accomplished physician and trusted ruler Lloyd, was the first physician elected to the Pennsylvania Hospital, and was what we would call Port Physician in 1725. He shared this duty with Thomas Græme, a Scotch physician, who arrived with Governor Keith in 1715. Besides being thrown into large practice by the death of Griffith Owen, this gentleman was at various times Naval Officer, a Councillor, Master-in-Chancery, and at last Chief Justice of the Supreme Court, for which we may note that he received £50 a year. He was the first president and the founder of the now ancient and still useful St. Andrew's Society for giving aid to destitute Scotchmen, assisted to create the Philosophical Society, was with Zachary, the two Bonds, Moore, Cadwalader, and Redman, of the first staff of the Pennsylvania Hospital, and died in 1772, Collector of the Port. On his tombstone in Christ Churchyard, it is said of him, and it would seem with justice, that

> "Peaceful through life, as peaceful, too, in death,
> Without one pang he rendered back his breath."

The men I have here so briefly described were, with the exception of the last, of the Society of Friends—Græme was of the Church of England. The great struggle between the Presbyterian settlers of the interior of the State and the followers of Penn was now in full tide. Already other sects than those of Penn began to be prominent, and henceforward we find physicians of eminence who were not of the creed of Fox, but neither in the seventeenth nor the eighteenth century do we observe in Pennsylvania what was very common in early New England and New Jersey—men doubly occupied as physicians and clergymen.

I should have found it difficult to say less as regards the notable personages who came and went on the scene of our Colonial history, and who brought to their medical work the tastes, manners, and education of gentlemen, and to its completeness, high-minded sense of duty. It was needful that I spoke of them in order to show how perfect has been the good fortune which, from the day when the "Welcome" brought us Thomas Wynne up to the present hour, has failed not to give us like men, gifted with like intellectual qualities, holding the same lofty traditions of honor and industry, ready to take up our unending task whenever an older and wearied generation laid it down.

The century was in its last third. A new group of physicians, nearly all young or in early middle age, and trained in an eventful war, had come upon the stage. The city contained about 45,000 people. It was the seat of Government and of the largest social life the land afforded. Still predominant in commerce, it was also active in education and science. The College of Philadelphia had been for a time suppressed, the University had been medically organized, the Federal constitution was in debate, and Washington, a man of fifty-six years, was resident in Philadelphia. Fitch was constructing his first steamboat.

It would seem that the College was organized some time in 1786, but as to this we have no record other than that just mentioned. The first meeting of which we have a minute took place on January 2, 1787, and to this date we have always referred as our natal day.

On that 2d of January, 1787, in the evening, in a little house used by the University, and known as Surgeons' Hall, on Fifth Street south of Library, assembled a portion of the notable group of men who then constituted this College. By the dim light of candles, for which I have found the modest bill, clad after the fashion of the day, some in Quaker dress and some in knee breeches, silk stockings, and low shoes with buckles, most of them carrying, I fancy, the gold-headed cane and the meditative snuff-box, some with queues or powdered wigs, a fading fashion, were John Jones, William Shippen, Jr., Adam Kuhn, Benjamin Rush, Thomas Parke, Gerardus Clarkson, Samuel Duffield, James Hutchinson, William W. Smith, Andrew Ross, William Clarkson, James Hall, William Currie.

The full roll of Fellows and junior Fellows in January, 1787, adds the names of John Rodman, John Morgan, George Glentworth, Abraham Chovet, Benjamin Say, Samuel Powel Griffitts, Benjamin Duffield, John Morris, John Carson, John Foulke, Robert Harris.

Before our charter was obtained in 1789, there were added Nathan Dorsey, John R. B. Rodgers, Caspar Wistar, Jr., James Cuningham, Charles Moore, Michael Leib, John H. Gibbons.

They were in all twenty-four when they met in January, 1787, and thirty-one when they were incorporated in 1789. Only three of their names are to-day represented on our present list; but many more are familiar to your ears, and if we include the men I have previously mentioned, you will find that a large share of the best known families of our city trace their lineage from one or other of this memorable group. It would, in fact, be easy to give you a long catalogue of families distinguished in our national and local history, or in our social life, who inherit the blood of one or more of the physicians I have named or have yet to name; but as some of those here present may have the misfortune not to be able to claim the honor of medical ancestry I generously refrain.

The portraits of many of these notable personages ornament our halls, and tell in their ruddy complexions of men who lived much out of doors, and often in the saddle, and illustrate the changes which time is making in the physical conditions of our race. Here are descendants of the settlers who, armed only with the courage of good intention, came to the wilderness with Penn, or followed soon after. Welsh or English, nearly all of them, but two represent the German element; only four have middle names—as to which a curious change is seen in the later years.

The older men generally sign first. The President was sixty-five; Jones, fifty-eight; Morgan, Shippen, and Kuhn, each fifty-one.

These were physicians who assisted at the troublous birth of a great nation. I fancy that I can see in their resolute faces the lines left by the sorrows and trials of those eventful years when they rode with the great Virginian, and shared with him the hardships of doubtful campaigns and the triumphs of Princeton and Yorktown. Among them were the friends and physicians of Washington, Franklin, Hamilton, Jefferson, and Adams. They held to their medical opinions, as we shall see, with the same absolute belief that controlled their political actions, and were nearly as ready to fight for the one as for the other. As to their medical ancestry, the best of them had been educated at Edinburgh, which school is the parent of our University. Genealogically, we might speak of our College and of the University as children of Edinburgh, and grandchildren of Leyden.

[Here followed terse sketches in words of the founders; of Rush, Dr. Mitchell said:]

With reverent doubt of my powers to do justice to the greatest physician this country has produced, I approach the task of briefly recalling to your memories the vivid and emphatic personality of Benjamin Rush. His life invites a less hasty biographer, and is full of such seeming contradictions as can only be explained by the belief that the earnest, decisive, and mutinous nature of a man, proud, rather than conceited, got the better of the principles by which he honestly strove to guide his conduct. That he won at last in this contest, was shown by the grief with which a nation mourned his death, when the poor in crowds besought a sight of his face, or, at least, to touch his coffin. Look at his portrait by Sully in our hall. It has the scholar's hands, the largely modelled head, the contemplative blue eyes of the observer, the nose and chin strong, firmness in the mouth, and a trace of too critical tendencies in the droop of the lines of the lips, withal a general expression of tranquil benevolence, a face like the man's life and character, full of dissimilars, with a grand total of good.

How shall I briefly bring before you the career of this restless being? Relentless energy drove him through a life in which ardent sense of duty, large-minded philanthropy, love of country, devotion to his art and its science, immense belief in himself, were the motives to industry, which made note-books the companions of his student youth, and which failed not until the pen fell from a hand enfeebled by the close approach of death.

He was a statesman, a scholar, an army surgeon, a punctual and careful physician, an actively religious man, a far-seeing and courageous philanthropist, and a sanitarian far in advance of his day. These are what I might call four careers, in all of which he excelled unaided by secretaries or modern means of condensing and relegating labor: one such suffices most men. He was a member of every important political assembly which met in this State while he lived. When timid men fell out of the Continental Congress, he was elected to that body, that he might sign the Declaration of Independence, and was the only physician whose name is on that energetic arraignment of the Crown. I have neither time nor desire to speak of his relations to Washington. He criticised him with his usual courage and with a severity in which at that time he was not alone, and, although later in life he somewhat relented, he never quite forgot the bitterness which arose out of his too famous letter, and to the end of his days looked upon the great leader as one not above the judgment of his fellows. As regards the patriotism of Rush there can be no doubt. It approached the earnestness of religion, and its very intensity made him unhappy and critical when others seemed to him to be showing that want of energy which in the first years of the war he thought was seen in the Fabian policy of Washington.

Rush was Surgeon-General to the Middle Department, and later Surgeon-General, and served faithfully in the New Jersey campaign and in the dreary camp at Valley Forge. He resigned in 1778, after his difficulty with his chief, and declined pay for his services.

As a broad-minded philanthropist, I view him with wonder. The higher education of women he urged as a special need of a Republic, and as boldly wrote of public punishments and against the penalty of death. With like courage he denounced slavery, or turned to demand legislation against the abuse of alcohol, or to implore care in the use of this agent in disease, and, although a scholarly man, eloquently represented the waste of time in the too general study by the young of the classical tongues.

On his medical career I cannot linger. His views as to bleeding were extreme. They were greatly modified in his later years, but have been misrepresented by the enmity his positive nature excited, and can be fitly judged, not by his occasional vigor of statement, but also by the many tempering remarks to be found in his works. His ideas on the contagion of yellow fever and its domestic origin excited the hostility of commerce, and embittered his existence; but, although as to the former he changed his beliefs later in life, as to the latter he seems never to have faltered.

I presume that he held his opinions tenaciously, and was so conscious of his own general superiority to those about him, that he found it hard to weigh their reasons justly. He says, "I early discovered that it was impossible for me, by any reasonings, to change the practice of some of my brethren." Then he adds, "humanity was therefore on the side of leaving them to themselves, because what is done in these consultations is the ineffectual result of neutralized opinions; for the extremity of *wrong* in medicine, as in morals and government, is often a less mischief than that mixture of *right* and wrong which serves, by palliating, to perpetuate evil." How interesting is this irritable confession, which tells so much more of the man than he meant to put into it. Let me add, as a thoughtful physician, that no one can read what he wrote—and I have

read most of it—without a strong sense of his sagacious and intelligent originality, and admiration of his clear and often fervid style. His work on insanity is a masterpiece. A recent English writer calls his book on "the bilious remitting yellow fever" a wonder, and says of that remarkable description of his sensations during the height of the epidemic, "it is as if he were talking to you, a ghostly whispering through a veil of nine-tenths of a century." He has been called the American Sydenham. He was not as I see it, so great a physician, but taking his whole career—and both were earnest republicans—Rush was the larger personage, and surely, next to Franklin, the greatest citizen of Pennsylvania.

His bitterest foes are best remembered because of the man they reviled. Even before death came to heal all wounds, he stood where few have stood in the estimate of men. He could not but feel this tribute. It gentled the positive and ardent nature, once ready to cross swords with all who dared to differ. He says "I was once an aristocrat, then a democrat, now I am a Christocrat." Certain of his words should have been placed on his tombstone. With them we may leave him to his repose, near the yet greater Franklin. "Posterity," he says, "is to the physician, what the day of judgment is to the Christian."

Caspar Wistar, Jr., is a familiar name. Like Rush, there is much of the man's life on record in the portrait by Otis, as the least observant may see. The face is strong and intellectual, the mouth large and full of good humor and mirth, the chin positive, a face thoughtful above, and below alive with promise of genial companionship. He could have been but sixteen when we hear of him as active in helping the wounded after the indecisive fight at Germantown.

He followed Rush as President of the Anti-Slavery Society, and Jefferson as President of the Philosophical. If a man's friends be in some sense a description of the man, among his were Humboldt, Michaux, Soemmering and Camper, Cullen, Hope, Jefferson, Warren, and Correa, the cynical and amusing Portuguese minister. You can see from these names, that science occupied him, and especially anatomy, that the practical aspects of his profession were not forgotten, and that he was at home among those whose talk left to their surviving contemporaries vivid memories of an unusual social era. He is known still to most of us as the founder of the Wistar Parties, which owed much of the later social vitality to the hospitable houses of the leaders of our profession. When I was a young man and Wistar was long since in his grave, we were still familiar with the worn card of invitation which carried his vigorous profile with its formal queue from simpler days to those of champagne and terrapins, and until the fierce quarrels of the great war broke up this gay and joyous company. It was wickedly said that the doctors profited by those noble suppers. Even in their luxurious decadence they were delightful. Men who came to eat remained to chat. They left to me at least a gallery of pleasant portraits of some whose living talk would have made that good founder happy. Hear how Thackeray mourns a dead friend. "There will be," he says, "no more Whister parties for him. Will Whister himself, hospitable, pig-tailed shade, welcome him to Hades? and will they sit down—no, stand up, to a ghostly supper, devouring the *ὀθόνιον ψυχαι* (the mighty souls) of oysters and all sorts of birds?" (*Hazed immemor.*, p. 8. William B. Reed, 1864, Phila.)

I have dwelt on this aspect of a full and wholesome, learned and useful life, because it well illustrates the social prominence of the Philadelphia physician. We may leave him with the words in which another described him: "Decorous, suave, honorable, and courteous, he forgot nothing except injuries."

The history of an old and learned institution is that of its members and of its relation to public affairs. No man can hope in the scope of an address to set before you the shining roll of the men who have illustrated our story with duty done simply and in private, of patient, charitable lives, of those larger existences which left their mark, also, on the science of their day, and to this memorable hour have sustained in noble succession the prominence of this city in all that lifts our art and its sister sciences above the common levels of applied usefulness. The task were hopeless and belongs to the historian rather than to the orator.

But our relation to the public cannot be thus readily disposed of. The acts of single men help to give us collective power to interfere in public matters, and here this College has been up to this day potently active. To it came early for advice in all affairs of health and quarantine the city, State, and general government; and the minutes amply record that it has labored conscientiously to aid the commonwealth and the city as to sale and importation of pure drugs, as to parks, water supply, education, drainage, and the many other problems which call for advice and direction from experts.

To the physician epidemics are his battlefields. His daily life is hard enough, and, unlike the soldier, he lives amidst constant perils, of which habit has made him negligently forgetful. He is assisted to be unthoughtful as to risks by the fact that the community thinks little of those which are not, like the soldier's, occasional, or which it does not largely share. You must have lost sense of heroism if you do not feel some thrill of pride when you look back with me over those sad years in which the Fellows of this College, amidst the contagion of terror, faced the storms of death which from 1793 to 1804 swept over this city and forever ruined its mere commercial supremacy.

Let us see how well this College met it. Several of its Fellows could recall the epidemic of 1762—the Barbadoes Plague—the dreaded yellow fever. Rush, a student, made notes of it in his constant way, and Redman, an older man, described it with accurate skill. A few hundred died, and for thirty-one years the great town flourished undisturbed. For two years the College had at times been urgent as to quarantine, but selfish, short-sighted commerce had been more potent. On the 25th of August, 1793, a special meeting of the Fellows was called "to consider their duty because of the fever of alarming nature." Rush, Hutchinson, Say, and Wistar were to report on the 26th. Nothing, on the whole, could have been better than the calm, good sense of the letter of public advice which the College, at the instance of their committee, addressed to the mayor, Mathew Clarkson, and to the people at large. At this meeting, the President describes the fever of 1762. Tilton, our associate, advises tents as hospitals, and the College decides to meet every Monday. How simple

it all sounds, the quiet councils, the talk as to treatment. The Fellows assemble on the 3d, 6th, 10th, and 17th of September, and consider Alexander Hamilton's letter of inquiry as to the fever and answer Warren, of Boston. Meanwhile the plague is on the people, and the College meets no more until November.

To speak of this awful summer, is to speak of a population degraded by the very insanity of fear. The rich fled first, and at last almost all who could go. In round numbers, Philadelphia had 6000 houses and 49,000 souls. Some 3000 houses were closed. 12,000 persons fled to the country—Carey says 17,000. Of those left behind, 11,000 took the fever, and one-third of these died. Before this appalling death-rate all but a rare few gave way. In deserted streets, between rows of closed houses, where commerce had ceased, men walked down the middle of the causeways, and declined to shake hands with friends, or turned aside from any who wore the badge of mourning. Thousands of both sexes smoked tobacco to avoid disease, or carried vinegar or camphor or bits of tarred rope for protection, while bonfires at night and firing of muskets to disperse contagion, ceased only when the mayor forbade them. The churches were shut; most of the weekly papers ceased to appear. For the laborer there was no work. Starvation drove him to crime, and thieves lived riotously in deserted houses. At last family ties were broken, men fled from their dearest, whole families deserted the bed where the father lay dying, nurses were hardly to be had, and still the sombre death-cart went its nightly round with its negro driver, and in answer to the dreary cry, "Fetch out your dead," corpses were lowered from open windows on to the cart, backed up on to the sidewalk, or were carried out in haste to be put across the shaft of what was called a chair, and hurried away for swiftest burial. So lower and lower men sunk, as the plague increased, until at times the dead lay unburied, corpses were found in the streets, and the climax of misery, neglect, and profligate riot was reached at Bush Hill Hospital for the poor. Amidst this horror of disease, of selfishness, of crime, there were men who grew morally stronger through that which enfeebled the mass. The most of the physicians of the blighted town went about their duties untouched by panic—undisturbed by fear. In our own ranks were none who failed. Their names are to be read on every record of those dreary hours. Theirs was what Ruskin speaks of as "that constitutional serenity in danger, which, with the wise, whether soldier or physician, is the basis of the most fortunate action and swiftest decision of deliberate skill." (Proterita, p. 379.) How they differed as to treatment, and how doggedly they held their beliefs concerns us little. That they did their full duty as honest gentlemen concerns us much.

Hutchinson died, and Morris and many others not in our fellowship. None altogether escaped untouched by the plague, which swept away ten physicians in a month. Says Rush, "at one time but three physicians were able to do duty outside of their own houses. From this cruel summer until 1806, no year left us free from the fever, but the worst of it fell upon us in 1798." Again the College had in vain sounded repeated warnings to the city, the State, and the General Government. Again there is that eloquent blank in our minutes from August to November. It was more terrible than '93. Some forty thousand fled, and of those who stayed, about four thousand died, nearly half of those attacked, and again the scenes of '93 were repeated, and again, as in '93 and '97, our ranks were thinned, and only more did not die because nearly all were protected by previous disease.

There were physicians who fled from this more deadly horror, but in the thick of it I find the names of our Fellows. Griffitts's daily record, meant only for his own use, is before me as I write. He says: "My patients are mostly among the poor. While I went to the country to see my sick child, half a day, upward of fifty knocks at my door. Yet through all this I am favored with calmness. My lot seems cast among misery and death. A day of trouble. Buried a beloved servant. Much unwell today. Too much to visit. Thus they suffer from unavoidable neglect. I feel indeed alone."

We lost Hugh Hodge and Annan later of the same disease, and through all of these sad years we find always ready, always dutiful, the best of the men whose lives I have sketched. Scarce one escaped the wounds of disease, and at least six died; but none failed us. Surely this is a record to look back upon with that pride which nourisheth good example. We may grieve for suffering, and regret careers cut short, and yet desire to preserve their remembrance;

> Nor could Immunity assign
> Each hour which bade her heart beat high,
> And blazoned duty's stainless shield,
> And set a star in honor's sky."

Meanwhile the battle as to contagion and importation, and bleeding, and emetics and calomel, raged with a fury of personalities for which it is difficult to account, but which the tenacity and irritability of Rush may, in a measure, explain. It caused Rush a bitter personal quarrel with Andrew Ross, and disputes between Rush and Kuhn as to the treatment of Hutchinson, and led to the resignation of Rush and the formation of the short-lived Academy of Medicine. These virulent intellectual duels ceased by degrees when the new dispute as to vaccination arose, and as most of our Fellows favored it, it seems hard to explain their action. In December, 1802, Lettsom sends the College from London vaccine virus, and shortly after is elected an Associate, while alas, Jenner, proposed by Plunket Glentworth, fails of election, a sad commentary on the too conservative tendencies which nowadays have somewhat ceased to trouble us. But a little while and the world of opinion was with Jenner. Three or four years later no man would have dared to blackball one of the immortals. The moral is not far to seek, and time has not quite worn it too threadbare for use. In all our history we have little to feel ashamed of, and this reproach comes swiftly after, nay, among the deeds which showed of what heroic stuff were the men whose portraits hang around our hall.

Our early years produced a few notable essays, but the great and active intellect of Rush was lost to us and his influence kept out of our fellowship Physick and Mease and some others of note. As I look forward over our minutes up to 1820 the papers are fewer. In some years there is not one. Often there is no quorum. Currie writes and tells us in a wandering and irritable letter, that we are inert and useless, which is hardly true, for still in all public affairs the College is active and attentive. Death, too, has been busy with the men who

had smiled in her face so often. Some twenty are gone—the surgeon-soldiers of 1776, the veterans of '93 and '98. New names appear, though slowly. Sixteen are added before 1807, and of these the yellow fever has taken four. In several years no election of a Fellow occurs, and none from 1807 to 1810. In 1811 we gain the first I personally remember, the honored and well-loved Hewson, sometime our president, then Chapman, of joyous and social fame, Neill, Parish, the Bartons, and Atlee at the beginning of his life of vigorous and originative usefulness. And now, in 1823, Currie, Parke, and Griffitts, alone, seem to be left of our institutors, but as to some others I can find no note. It is difficult to explain the intellectual inactivity of the College in these years. It was rather paresis than paralysis, inertness than want of power. But why did we survive at all? The Academy had perished, the Philadelphia Medical Lyceum had come and gone. The Philadelphia Medical Society, the Kappa Lambda, the Medical Association of Philadelphia had been organized and were soon to die out or had already disappeared.

We were saved, I fancy, by that which preserves the vitality of families—great traditions which nourish pride and the conservative power of property—careful treasurers had begun to hoard for us a little money, and our library, if as yet small, was valuable. Moreover, we were still, as always, the public advisors, and the position of advisor is one which flatters. Then came the fortunate accessions from 1824, and we win illustrative force as we get Hartshorne, Bond, Hodge, Meigs, La Roche, John K. Mitchell, Darrach, and notably Wood and Bache, familiar collocation of names, and almost as one in friendship and usefulness: Pennock and Gerhard, Hays, Pancoast, Mütter, Carson, Dunglison, Norris, McClellan. Catalogues of names are valueless, but these are winged with memories.

We met first on Fifth Street. In 1791 we carried ourselves and our modest library—one case of books—to the Philosophical Society rooms, whence we journeyed to the Mercantile Library building, then on Fifth Street, and in 1854 to the little house on Spruce, within the Hospital grounds. As I first climbed its well-known stairs in 1856, I remembered the picture by West, of Christ healing the sick, which in my childhood hung on the wall. The debates used to be sharp in those days. There was Wood in the chair, most courteous of men, gently formal, and of ever ready kindness to younger physicians; a peace-making presence when the too positive Condie was raging in debate, and Charles Meigs, with his poetic nature and talk of singular freshness, was spurred to sharp reply, and Hodge grew graver and yet more sedate, and Bache sat ready to drop with deliberate slowness of contradiction on the inaccurate. As I write, the visage of Gerhard returns to me with its grim humor. A man quick of speech and as quick to regret, an unbalanced nature, but a keen and subtile observer. There is stout George Fox and the slight, delicate figure of La Roche beside our great surgeon, Pancoast, sturdy, earnest, and original, a curious physical contrast to his colleague Mütter, small, exquisitely neat in person and courtly in manner.

You will forgive my gossip. I should like to believe that our juniors have reason to look up to us as we did to these men. A crown seemed as remote to me then as the chair which, by your grace, I now hold.

We owe our present home chiefly to the liberality of George B. Wood, to George Fox, and to the unceasing efforts of Isaac Hays, who, as chairman of our Building Committee, served the College with that high-minded sense of duty which he carried into every relation of life.

In 1856 our building fund, by careful nursing, had grown to $16,000. Our first large accession, like much else that is good, came from Wood. A western quack had infringed the copyright of the Dispensatory, and the heavy damages awarded were generously given to our building fund. In the same year, by good fortune, Thomas Dent Mütter offered to give us his museum and to leave us an endowment of $30,000, on condition that within five years we gave this collection a fire-proof shelter. Gift after gift from Dr. Wood followed—not less than $10,000 in all—and in 1863 we moved to our present hall, to which we have but of late added the third story contemplated in the original plan.

The College museum at once grew into importance by the addition of Mütter's gift, and is now one of the most valuable and interesting collections in America.

The library, which owed its first gift and legacy of books to John Morgan, now numbers nearly 38,000 volumes and some 20,000 pamphlets, and is second in America only to that which the ample purse of government and the genius of the greatest of medical bibliographers, John S. Billings, have created in Washington.

Books are the best tools of our business, and a great library like ours insensibly educates by tempting men with the noblest of opportunities. It is like an unfailing friend to whom we go for counsel and helpful advice, and a catalogue is its ready memory of all that our greatest knew and taught. Look around that great collection in all tongues. It is a vast presentation of the thoughts, the beliefs, the victories, the defeats of that profession which has been, as compared to any other, the purest, the most single-minded, the most simply devoted to its moral creed, the world has seen through all its changeful ages. It has its peerage, its lords of thought, its sturdy, practical commons. Yet here is no set creed of dogmatic beliefs. We make and unmake our rulers, and time, which is more wise than Bacon, has a large vote in the matter; but while systems of medicine crumble, and doctrines have their little day, and men have been intellectually right or wrong, it is pleasant to remember that the lofty code of moral law our Greek fathers taught has kept through all these productive centuries an invigorating control over the lives these gathered volumes represent. Thus, for him who loves his art, a great medical library is full of lessons in the conduct of life. There, side by side, the feeblest and the strongest meet. What a record of the follies and caprices of learning, of devotion, of martyrdom, of simple usefulness, of ambitious failures! Here are stately tomes unread for ages. Here is some little volume which has changed the great currents of thought and brought hope and relief to a thousand bedsides. In yonder corner is a modest book-case, which groups the bric-a-brac of the bibliographer; the mad jesters, the cranks, the queer anecdotists, the priceless incunabula, the medical poems.

I like to think of the book-loving men to whom we owe this collection. Morgan, the scholarly; Hays, editor for fifty-three years of the best medical journal

the world has seen; Moreton Stillé, too early dead, with his half-used store of varied learning; Wood, Betton, Mütter, Gross the great surgeon, Hodge the famous teacher of obstetrics; Lajus, that gentle and modest scholar who once said to me in his odd way, "I like the men who are like books, and that is why I like Samuel Lewis."

I have broken my rule for the first time, to name a living Fellow of the College, the constant benefactor of our library; but in proportion as a man is modest, self-forgetful, prone to avoid public recognition, one is tempted at a time like this to say what we think of him to whom we owe so much. Kindly friend, learned and liberal scholar, we are glad that you are here with us to know, once for all, how lovingly we thank you for the unstinted generosity of these many years.

In that last great war we most of us so well recall—in that vast struggle, whose authors we do well to forgive, but whose trials and lessons we do as well never to forget, this College was true to its traditions.

There are on our list to-day, at least one hundred and four men who served their country in the field, in hospitals, or at sea, in those years of sacrificial trial.

Whatever we may have thought or felt of that section of our race which faced us in fight, of this at least I find it a pleasure to feel sure, that wherever men were sick or wounded, our ancient guild did well its Christ-like duty. As to that record, North and South, there can be neither doubt nor difference.

I close with satisfied pride these annals of the past, and its dead. I see about me men whose books are in every tongue of Europe, whose works are known and honored among the learned of every land, men who wear by just decree of their fellows the unseen crowns of honorable estimate. I see, too, the young in work, the men who are to follow us. To them we shall soon consign this precious heritage, the record of a century of duty; an hundred years without one break in our meetings, save when pestilence thrust upon us a more imperative service. There is that in these years to make them proud of a fellowship which in war and in peace has left us examples of single-minded workers unknown to fame, of the charity without taint of selfishness, of heroic lives lost in battle with disease, of gentle scholars, of daring surgeons, whose very fingers seemed to think, of physicians rich with every professional grace. The pride of lineage is valueless which does not secure to the future vitality of usefulness, and I must have told my story ill if to every physician who hears me its illustrations have not the invigorating force of moral tonics.

I turn now from the present and face the silence of futurity. As earnestly as our first president, I pray with him that all those who sit around me, and all who are to come, do publicly and privately serve their generation.

Feeling, like him, the weight and dignity of my office, and to-day more than ever, I look onward thoughtfully to that next centennial time. Every heart that beats in this hall to-day will have ceased to pulsate. Another will stand in my place. Reviewing our works and lives, he will be able, I trust, to say as confidently of us as I have said of your fathers—these, too, belonged by right of dutiful lives and sincere work, to our great, undying brotherhood.

2*

ORIGINAL ARTICLES.

A PRELIMINARY NOTICE OF A CRYSTALLINE ACID IN URINE POSSESSING MORE POWERFUL REDUCING PROPERTIES THAN GLUCOSE.

BY JOHN MARSHALL, M.D.,
DEMONSTRATOR OF CHEMISTRY, UNIVERSITY OF PENNSYLVANIA

In the early part of last November, Prof. Frank Donaldson, Sr., of Baltimore, sent for examination, to Prof. Tyson, of this city, a urine which contained a substance having strong reducing properties much resembling those possessed by glucose. After Prof. Tyson had finished his examination, he gave the remainder of the urine to Prof. Wormley, for further investigation. From Prof. Wormley it came to me. From the results obtained by the three independent observers it was concluded that the reducing substance was certainly not glucose. This conclusion was at once communicated to Prof. Donaldson by Prof. Tyson, and at the same time Prof. Tyson requested that a larger quantity of urine be sent to me for further examination. This larger quantity was kindly sent by Prof. Donaldson, and arrived at the University on November 17th, and the examination was immediately continued. A few days afterward (November 21) crystals of the lead salt of the acid were obtained. Prof. Donaldson was at once informed of this result, and at the same time a few crystals of the salt were sent to him.

From Prof. Donaldson it was learned that the urine in question was voided by a man thirty-seven years of age, of florid complexion, and of average height and weight. His general health and nutrition have always been good. He has never had any muscular weakness or inordinate thirst, no emaciation, but instead a continued increase in weight, no excessive quantity of the secretions. He has always been temperate as to alcoholic stimulants. Since his seventeenth year he has been engaged in the lumber business, and at present is superintendent of a planing-mill, which position requires his visiting the mill two or three times daily.

The case is peculiarly interesting, because of the man's having repeatedly, during the past two and a half years, applied to the various life insurance companies represented in Baltimore for insurance, but each time suffering rejection because of the response of his urine to certain reagents used in testing for glucose, a response which naturally was considered to be due to glucose.

Upon the ingestion of certain substances, other substances appear in the urine, which have a reducing action upon alkaline copper solutions. When camphor is ingested, camphoglycuronic acid, $C_{16}H_{24}O_8$, appears in the urine. This breaks up into glycuronic acid, $C_6H_{10}O_7$, which has a strong reducing action. Chloroform in the urine also reduces alkaline copper solution. Chloral is converted into urochloralic acid, $C_8H_{11}Cl_3O_7$. Turpentine into terpenoglycuronic acid. Morphia forms a reducing substance. Phenol (carbolic acid) and benzol form hydrochinon, $C_6H_4(OH)_2$. Phenol and benzol are also converted into oxyphenic acid (pyro-catechuic

acid), $C_6H_4(OH)_2$, which latter probably is identical with [illegible] ton. Tannic acid is excreted as gallic acid. All these products possess the property of reducing alkaline copper solution. Hydrochinon and oxyphenic acid in the presence of an alkali, and when exposed to the air absorb oxygen, and turn first green, then brown, and, finally, black.

It was learned that the person who voided the urine under examination never had occasion to use any of the above-named substances; and, therefore, one would hardly expect to find the products of their metamorphosis in the urine. It must not be forgotten, however, that oxyphenic acid has several times been found in normal urine.

The peculiar acid in question is contained in rather large quantity in this particular urine, nearly one gramme of the lead salt having been obtained from 100 c. c. of the urine. Its reducing power is greater than that of glucose; 0.6 c. c. of the undiluted urine was sufficient to reduce the cupric oxide in 10 c. c. of Fehling's solution, equivalent to 0.05 of glucose, or, expressed in glucose units, equivalent to 8.3 per cent. of glucose.

Some of the reactions of this urine, when considerably diluted with water or with normal urine, strikingly resemble reactions often noticed in this laboratory in urine considered and acknowledged to be free from glucose, especially in the reaction with diluted Fehling's solution. With the urine containing the acid, diluted either with water or with normal urine, and diluted Fehling's solution, a brownish and sometimes greenish coloration is produced, but no appreciable reduction of the cupric oxide is observed. A similar result has often been noticed in this laboratory when a presumably normal urine has been tested with Fehling's solution.

It is quite likely that this acid may occur more frequently in urine than is suspected, probably only in less quantity than contained in the urine just referred to, and to its presence possibly may be attributed the many peculiar and unsatisfactory reactions so often noticed when testing urine with Fehling's solution. Quite likely, too, in some samples of urine, the acid may be contained in sufficient quantity to produce a reduction with Fehling's solution in such a satisfactory manner as to be mistaken for glucose, and thus many erroneous diagnoses of diabetes mellitus may have occurred.

The urine from which the acid was obtained was of a brownish-red tint, perfectly clear and without sediment.

To isolate the acid the following method was employed:

The urine was treated with half its volume of plumbic tribasic acetate solution, and the resulting voluminous precipitate collected on a filter and washed several times with a mixture of equal parts of alcohol and water. The precipitate was then suspended in warm water and hydrogen sulphide passed through until all the lead was precipitated. After expelling the hydrogen sulphide from the filtrate by boiling, excess of plumbic carbonate was added, and the liquid was gently boiled several minutes, and then filtered while hot. The filtrate was concentrated on the water bath and then kept in a cool place to allow crystallization to occur. The crystals of the lead salt which separated were washed by decantation with a mixture of equal parts of alcohol and water and recrystallized from hot water. Finally, when sufficiently pure they were dissolved in hot water and the lead precipitated by hydrogen sulphide, filtered, and the filtrate containing the free acid evaporated to dryness at about 70° C. The residue was extracted with ethyl ether, and the latter evaporated spontaneously. Several recrystallizations from ether, the final one from a mixture of ether and water, are necessary to obtain the acid in a fairly pure condition. The crystal mass was pressed between bibulous paper and again recrystallized from water.

The acid thus obtained crystallizes in opaque white tetragonal prisms, melts at 140° C., and sublimes in the same prismatic form, the crystals generally radiating from a centre. It is very soluble in water and in ethyl ether, soluble in absolute alcohol and also in ordinary alcohol, sparingly soluble in chloroform, insoluble in benzol, toluol, and in petroleum ether.

When its solution in ethyl ether is evaporated at a temperature of about 60° C., a slight claret-red tint is produced, which soon resolves into spots of purple. This purple substance (somewhat resembling murexide) attaches itself to the crystalline mass, producing a very beautiful appearance. The crystals, including the purple substance, dissolve in water, with a disappearance of the purple coloration. In the spontaneous evaporation of the aqueous solution of the acid no change of color is noticed.

The acid does not contain sulphur or nitrogen.

The acid is absorbed by animal charcoal. When the urine itself is passed through animal charcoal the filtrate becomes dark claret-red in color, and has lost its reducing property.

Sodium hydrate gives a brownish coloration, beginning at the surface of the liquid (due to absorption of oxygen). Oxyphenic acid gives an almost similar reaction, only that a green coloration is first produced, which is not the case with the other acid. The brownish coloration noticed when the diluted urine containing the acid is added to Fehling's solution, is partly due to the action of the alkali of the Fehling's solution upon the acid.

Picric acid causes no change. Upon the addition of sodium hydrate to the mixture of the acid and picric acid, a brownish coloration is produced, similar to that produced by sodium hydrate alone.

No reduction of the bismuth salt in Böttger's test occurs with the acid.

The acid responds to Trommer's test, as also to Fehling's test.

Argentic nitrate is reduced in the cold by the acid.

The fermentation test fails completely.

Its aqueous solution has no effect upon polarized light.

Upon the addition in turn of a dilute neutral solution of ferric chloride, ammonium hydrate, and acetic acid, the play of colors from green to violet, and then to green as with oxyphenic acid, does not

occur. It does not respond to the tests for hydrochinon.

With a dilute neutral solution of ferric chloride a blue coloration is produced which very soon disappears. From this reaction the acid most likely is a phenol derivative. It forms lead, barium, and calcium salts.

The lead salt crystallizes in heavy needle-like prisms, melting at 209.5° C. It is soluble in hot water, insoluble in benzol, toluol, petroleum ether, absolute or ordinary alcohol, ethyl ether, and chloroform. It is decomposed when passed through animal charcoal, the acid remaining in the charcoal and the lead coming through with the filtrate as oxide.

On account of insufficiency of pure material—acid and lead salt—no ultimate analysis has thus far been made. In a short time I hope to have enough material for that purpose, and then a formula for the acid can be constructed, and more learned regarding its source in the human organism. However, two lead determinations in the lead salt have been made:

0.1466 gramme lead salt gave 0.0717 gramme $PbSO_4$, equivalent to 33.50 per cent. of lead.

0.1314 gramme lead salt gave 0.0649 gramme $PbSO_4$, equivalent to 33.66 per cent. of lead.

Mean percentage of the two determinations, 33.58 per cent. lead, indicating that the acid has probably a high molecular weight.

I would suggest for this substance, provisionally, the name glycosuric acid.

MEDICAL CHEMICAL LABORATORY, UNIVERSITY OF PENNSYLVANIA

INFLUENCE OF THE RECENT EARTHQUAKES IN CHARLESTON UPON HEALTH.

BY JOHN GUITÉRAS, M.D.,

PASSED ASSISTANT SURGEON U. S. MARINE-HOSPITAL SERVICE, PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE IN THE MEDICAL COLLEGE OF SOUTH CAROLINA, AND ONE OF THE PHYSICIANS TO THE CITY HOSPITAL, CHARLESTON

It may be of interest to have the subject of the Charleston earthquakes presented from a different point of view than that taken by my respected friend and colleague, Professor Porcher, in THE MEDICAL NEWS of Dec. 11, 1886.

It is doubtful whether the pathological manifestations produced by the great disturbance are worthy of any special investigation. But the electrical hypothesis advanced by Dr. Porcher should not be allowed to go without comment. The public press has been busy with innumerable theories concerning the causes of earthquakes. The electrical theory seems to have captivated the public fancy. Seismologists, however, have shown that electricity has nothing to do with earthquakes, either as cause or effect.

I have not found the slightest evidence of an electrical disturbance accompanying these earthquakes. I believe that the reports of electric physiological phenomena grew *pari passu* with the diminution of the intensity of the quakes, and with the development of electrical theories in the public press. These reports appear to be biassed by the excitement of the imagination, or by preconceived notions, and their value is much diminished by the unmistakable hysteroidal impress which they bear.

If any precise evidence is wanted of the absence of electrical phenomena, it is to be found in the behavior of all forms of magneto-electric apparatus during the earthquakes. Barring the mechanical disturbances, it will be found that no effect whatever was produced upon these instruments, nor was the magnetic needle in the least affected.

The pathological effects produced by the earthquakes may be grouped under three heads: the *mechanical*, the *nervous*, and the *infectious* or *epidemic*.

First. The *mechanical*. The gross injuries need not be detailed here. All honor to the surgeons who did so manfully their duty in those trying times. I shall mention under this head a severe form of conjunctivitis and keratitis which became very prevalent. My friend Dr. Charles W. Kollock ascribes it to traumatism produced by particles of lime and other débris. The inflammation was frequently accompanied with superficial and painful ulceration of the cornea. In my own case, and, in fact, in the majority of cases it was found necessary to assist the local treatment by the use of stimulants and tonics.

Second. The *nervous* effects. These are well described in the paper of Dr. Porcher. The majority of them were evidently hysteroidal. Of these, some were actually experienced, but others, more particularly the so-called premonitions, were but fabrications of the after-thought, or innocent self-deceptions. The functional disturbances that were not hysteroidal may be set down as symptomatic of shock, of fear, and of a form of vertigo akin to sea-sickness. With these belong the vomiting, the diarrhœa, and the frequent micturition. I have no doubt that the severe shock produced, in some cases, more profound and lasting organic changes in the nervous system. Amongst such, perhaps, may be placed two cases of multiple neuritis that developed within the two days following the great earthquake. One of them was accompanied with pulmonary embolism and gangrene of the lung.

Third. In regard to what I have called the *infectious* or *epidemic* effects of the earthquakes there must be considerable doubts. Certain it is that a mild fever prevailed during the months of September and October, and that it went by the name of *the earthquake fever*. It was characterized by catarrh of the air-passages, irregular pains, some fever, and occasionally gastro-intestinal disturbances and jaundice. Some suspicions of dengue were at first aroused, but they were soon dissipated. The disease was, in my opinion, influenza. Late in the fall of 1885 we had, in Charleston, an epidemic of this disease; this persisted through the winter. The pulmonary complications were quite severe. During the summer months the epidemic gradually subsided. The earthquake, by bringing together so many of the inhabitants from all classes and places, I suppose, gave a wider distribution to the disease. It now assumed a different form. We had the simple

catarrhal fever with occasional cases of the gastro-intestinal and the rheumatic varieties.

Of course, it is difficult to prove that these effects were not due to exposure. Two facts, however, militate against this view, namely: the frequent presence of symptoms that were not exclusively catarrhal, and the warm and dry weather that prevailed during the seismic period. I may add that the recrudescency of the catarrhal epidemic is culminating at present (December 16th) in an epidemic of pneumonia of low type.

I shall state, in conclusion, that the malarial fevers were unusually prevalent. The mortality statistics show an increase of the number of deaths from this cause over the previous year, during the autumn months. But I do not think that they indicate any unusual severity of the type of these fevers.

I have made an abstract from our weekly bill of mortality, for the months of September, October, and November of this year, for purposes of comparison with the previous year:

[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
Other acute gastro-intestinal and hepatic [illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
Malarial fevers	37	17
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]
Exposure: earthquake	9	
[illegible]	[illegible]	
Injuries received: earthquake	40	

It is to be remarked that many deaths due to special causes were placed under the general heading of shock and exposure, mainly with the purpose of inducing the people to leave their encampments and return to their homes.

AN ACCIDENT WITH THE "A.-C.-E." MIXTURE.[1]

BY JOHN H. PACKARD, M.D.,

[illegible]

Mr. W., æt. forty-four years, was operated on for strangulated hernia June 13, 1886, in a Southern city. Anæsthesia was induced, without any unpleasant symptom, by means of the "A.-C.-E." mixture (one part of alcohol, two of chloroform, and three of ether). A portion of omentum, being adherent, was left in the sac outside of the ring.

He came to Philadelphia in July, and placed himself under the care of Dr. B. Trautmann, who kindly asked me to see him, an abscess having formed close to the neck of the sac. On the 14th this was explored and drained, pure ether being administered by Dr. J. M. Fox.

Later, a detached mass of omentum was detected in the scrotum, and on the 4th of September he was anæsthetized for its removal. He earnestly requested that we would let him take the "A.-C.-E." mixture, saying that it was much more agreeable to him than the ether alone. A pint of the mixture was put up by a druggist of high standing, and about ℥ij were used. Dr. D. Longaker took charge of the administration, which was without mishap.

After this operation, the scrotum swelled considerably, and there was much pain, relieved to some extent by the removal of two or three of the sutures. The swelling, however, remained, and it became clear that it was due to the presence of a mass of blood-clot, which would be only very slowly absorbed. With a view to the removal of this, on the 28th of September Dr. Trautmann administered the mixture from the same bottle, using, as before, a towel folded into a cone. I had nearly finished the evacuation of the clot, which, of course, took but a short time, when I perceived that the patient's face and lips had become ghastly pale, and that he had stopped breathing; I sought for the pulse in his groin, but could not feel it. We instantly lowered his head and raised his feet, and made artificial respiration by Sylvester's method. Dr. Trautmann gave him two hypodermatic injections of brandy. Under this treatment restoration was gradually effected; the operation was finished, and a rapid recovery ensued.

Mr. W. is a man of short stature but vigorous frame, temperate and correct in his habits; his urine is free from sugar or albumen. He had had hypodermatic injections of morphia nightly for some time to allay his pain.

So far as my knowledge goes, only one instance has been recorded in which death is said to have resulted from the inhalation of the "A.-C.-E." mixture. This case occurred in the Pennsylvania Hospital, in the practice of Dr. Hewson.[1] Only a very brief and incomplete account is given of it. It is simply stated that the patient, a robust man aged thirty-five, died in convulsions, which came on before complete anæsthesia had been induced. Dr. Morton, who was present, informs me that the death took place on the operating-table.

Dr. J. C. Reeve, an acknowledged authority on anæsthetics, wrote[2] in 1882 that this case was the only one so far known. Mr. Lister, however, in 1883,[3] says:

"The dread of the depressing effect of chloroform on the heart has led some surgeons to use it mixed with ether, together with some alcohol to produce complete blending of the two liquids. Deaths have, however, occurred under the use of such mixtures, and we have no evidence that they are really safer than undiluted chloroform carefully given."

A few references to published (or unpublished) cases in point would have added to the weight of this statement. Without asserting that such reports do not exist, I can only say that they have escaped my eye or my memory.

I do not overlook the fact that there may have been many cases in which, as in the one I have reported, a fatal result was happily averted, and it

[1] Read before the Philadelphia Academy of Surgery, November, [illegible].

[1] Amer. Journ. of the Med. Sciences, October, 1876, p. 415.
[2] Holmes's System of Surgery, Am. ed., vol. iii., note on p. 555.
[3] Holmes's System, 3d English ed., vol. iii. p. 623.

was never thought worth while to put them upon record. But this remark would apply equally to all other anæsthetics or anæsthetic mixtures.

If Hewson's case be regarded as a chloroform-death, it belongs in the small category of those which have been preceded by convulsions. My own case, on the contrary, was, in onset, symptoms, remedies effectual, and mode of recovery, similar to the great majority of those on record.

Reeve, indeed, says[1]: "Ether, in the human subject may produce death as suddenly, as unexpectedly, and in the identical manner that chloroform does." But, with all respect for his authority, I must say that my own search for such cases among those recorded has been fruitless. In every instance there was either previous disease, or some pathological condition discovered after death, which, at least in great measure, accounted for the fatal result. Thus, in a case reported by Lowe,[2] at first sight very like a chloroform-death, both lungs were found studded with hard, cancerous nodules, the liver was adherent to the diaphragm, and the heart was fatty.

It will be remembered by every one that it was argued in regard to the combination of ether and chloroform, with or without the addition of alcohol, that the greater density of the chloroform, and the more rapid evaporation of the other ingredients, would bring about a change in their relative proportions, so that the patient would come to inhale chloroform almost or quite by itself, or at least that the latter would be in dangerous predominance. In the present instance care was taken to shake the bottle before its contents were administered.

Several leading pharmaceutical chemists have assured me that there is no means of ascertaining the degree of combination or separation of the ingredients of the mixture. An experiment made by myself as to the inflammability of different layers of the liquid was without result.

Although during thirty-three years my experience with anæsthetics has been large, the case now detailed is the first one, if my memory is correct, in which I have myself employed the A.-C.-E. mixture, and it seems to me to afford proof that the dangers of chloroform are in no degree lessened, even by the thorough admixture of alcohol and ether. Until 1864 I used chloroform and ether indifferently; but in that year two accidents (one fatal) to patients under my care made me abandon chloroform almost wholly. I say almost wholly, because it may, under certain circumstances, be preferred, as when, for instance, in an operation on the face it is necessary to use the actual cautery, or to employ gas- or candle-light. It may also answer better for children requiring tracheotomy, as less likely than ether to induce congestion of the lungs. But, in my opinion, it is criminal carelessness to use this powerful and dangerous article without means at hand for combating its effects, if need be: brandy, ammonia, a hypodermatic syringe in good order, and a galvanic or electric battery.

My own conviction is that pure anhydrous sulphuric ether is the safest anæsthetic now available for general surgical purposes. Among the thousands of administrations of it at which I have been present not one death has occurred analogous to those so abundantly recorded from chloroform; nor have I ever seen threatening of such an event. I believe it to be entirely safe, except in cases of albuminuria, or perhaps in those of grave organic disease of the brain, heart, or lungs. In old or feeble persons congestion of the lungs may follow its use. The most unpleasant symptom I have seen caused by it was the epileptiform condition apt to be met with when the administration has been prolonged; but this easily yielded upon the withdrawal of the ether for a few moments, and it has never in my experience entailed any permanent ill effect.

Whatever anæsthetic be given, it is very desirable that the duty of its administration should be confided to an assistant, who should carefully watch its effects, paying no attention to anything else. Especial vigilance is called for in those cases in which the patient, as the saying is, "takes the ether badly."

Although the discussion as to the choice of anæsthetics, so actively carried on a few years ago, has subsided, the question was never definitively settled. It has not, however, lost its importance, and it can hardly be necessary to offer an apology for recording a clinical experience bearing upon one of its phases.

MEDICAL PROGRESS.

COLLECTIVE STUDY OF CENTENARIANS.—An analysis of the results of an inquiry issued by the Collective Investigation Committee of the British Medical Association has yielded the following interesting data:

Age.—Fifty-two returns; average age, about 102½.

Male or Female.—Fifty-two returns; M. 16, F. 36.

Single: Married: Widowed.—Fifty-two returns; S. 11 (of these 10 were females), M. 5, W. 36.

Affluent: Comfortable: Poor.—Fifty returns; A. 3, C. 28, P. 19.

Fat: Spare: Average.—Fifty returns; F. 9 (of these 8 were females), S. 23, A. 18.

Full-blooded: Pale: Average.—Forty-six returns; F. 8, P. 14, A. 24.

Strong: Feeble: Average.—Forty-eight returns; S. 20, F. 12, A. 16.

Figure: Erect or Bent.—Fifty returns; E. 25, B. 25.

Height.—Males: Twelve returns; average, about 5 ft. 8¼ in.; one also returned as short. *Female:* Twenty-six returns; average about 5 ft. 3 in.

Weight.—Males: Seven returns; average nearly 138 lbs. *Females:* Ten returns; average about 129 lbs. Respective Weights. *Males:* 182, 165, 147, 140, 120, 112, 98 lbs. *Females:* 196, 154, 140, 136, 126, 126, 120, 112, 112, 70 lbs.

Voice.—Forty-seven returns; loud, 6; clear, 16; weak, 7; full, 3; loud and clear, 8; full and clear, 6; loud and full, 1.

Hearing.—Forty-nine returns; good, 22; indifferent, 17; bad, 9; deaf, 1.

Joints.—Forty-seven returns; natural, 37; stiff, 4; deformed, 3; stiff and deformed, 1; the last was stiff from chronic rheumatism, and deformed from contrac-

tion of palmar bones, slightly deformed; 2, one of these was "from rheumatoid arthritis."

Sight.—Fifty-one returns; of these, 34 had good sight; 6 had cataracts, in one case unilateral, in another commencing; in 8 others, failure of eyesight was reported, apparently independent of presbyopia.

Glasses.—Thirty-five returns; 28 used glasses, 7 did not, but of these 4 were returned as "poor," and were possibly unable to read; 6 had used them for 40–50 years, 5 for 30–35 years, 4 for 10–20 years, 2 for 4–6 years, 5 for "many years," 2 for "few years." One had used spectacles for many years, but for the last twelve years had been able to read without them; another had not used them for twelve years; another "not for many years," but one "cannot now get them strong enough."

Digestion.—Forty-seven returns; good, 40; moderate, 7.

Appetite.—Forty-eight returns; good, 36; bad, 2; moderate, 10.

Eater.—Forty-six returns; moderate, 25; small, 9; large, 12.

Number of Meals Daily.—Forty-three returns; average number rather more than 3 daily; the greatest number was 5 daily (in 1 case); the least number was 2 daily (in 5 cases).

Alcohol.—Forty-six returns; none, 15; little, 24; moderate, 6; great deal of beer, 1.

Animal Food.—Forty-one returns; none, 3; moderate, 10; little, 23; very little, 2; much, 1.

Bowels.—Forty-three returns; daily, 26; alternately, 6; irregularly, 11.

Aperients.—Forty-one returns; rarely, 22; never, 14; frequently, 5.

Disposition.—Forty-six returns; placid, 14; irritable, 8; energetic, 11; placid and energetic, 8; irritable and energetic, 5.

Intellect.—Forty-six returns; average, 29; low, 5; high, 11; childish for six years, 1. One was said to be "slow in comprehending questions, but smart in reply."

Memory.—Recent Events: Thirty-nine returns; good, 26; bad, 6; moderate, 7. *Past Events:* Forty-seven returns; good, 39; bad, 4; moderate, 4. One "remembers and will quote a great deal of the Bible," another could "repeat about 100 Psalms correctly."

Habits.—Forty-eight returns; active, 26; sedentary, 15; bedridden, 7; of these, 4 were males and 3 females; one, a male, had been bedridden for 1 year, and one, a female, for 7 years.

Out-of-door Exercise.—Forty-five returns; bedridden, 7; none, 16; of these, one "can walk very well," another "stays in bed in cold weather;" little, 9; one of these "mended the thatch of her cottage at 96, and was always the first home from church, being a rapid walker;" moderate, 1, she "goes to church twice on Sundays;" eight walk out; of these, one "walked four miles yesterday," another "walks daily half a mile, can walk three miles," another is "fond of sawing firewood;" two still work, one of these "attended Hexham market, two years ago;" one "worked in field at 102;" one was "much out."

Smokes.—Forty-five returns; much, 7; four of these were women; little, 2; one was a woman; moderate, 3; one was a woman; none, 32; chews, 1.

Snuff.—Forty returns; none, 37; much, 1; this a woman, who also smoked a little; little, 2; one being a woman, who did not smoke, the other a man who smoked a little.

Sleep.—Forty-four returns; good, 32; bad, 5; moderate, 7. *Number of Hours:* Twenty-nine returns; average, rather more than 8½ hours; 3 slept 12 hours; 8 slept 10 hours; 1 slept 4 hours; and 2 slept 6 hours.

Hour of Going to Bed.—Thirty-five returns; average, about 9 o'clock, one retired at 12 o'clock, one at 11, and 5 at 7 o'clock; 7 were bedridden.

Hour of Rising.—Thirty-five returns; average, about 8 o'oclock; six rose at 6 o'clock, one at 5 o'clock, nine at 10 o'clock, one at 11 o'clock, and one at 4 P.M.

Chest-girth in Inspiration.—Male: Six returns; average, 36¼ inches. *Female:* Nine returns: average, nearly 31 inches. Male and female together, average about 33 inches.

Chest-girth in Expiration.—Male: Five returns; average, about 36½ inches. *Female:* Seven returns; average, nearly 30 inches. Male and female together, average about 32½ inches.

Elasticity of Rib-cartilages.—Male: Six returns; distinct, 1; indistinct, 5. *Female:* Thirteen returns; distinct, 5; indistinct, 8.

Pulse.—Twenty-nine returns; average, 74.75 per minute. In some cases, disease of the heart or lungs was returned, and in others the pulse-rate was unusually high, and the condition of the heart and lungs was not detailed; excluding these cases, eleven in number, the average becomes 69.70 per minute. *Regular, Irregular, Intermittent:* Twenty-eight returns; R., 24; Irr., 1; Int., 3. *Large, Small, Moderate:* Twenty-seven returns; L., 9; S., 17; M., 1. *Compressible, Incompressible:* Twenty-eight returns; C., 24; I., 4.

Arteries.—Male: Nine returns; even, 4; knotty, 2; tortuous and knotty, 1; tortuous, visible, and even, 2. *Female:* Twenty returns; even, 8; tortuous, visible, and knotty, 3; visible and tortuous, 2; tortuous, visible, and even, 1; visible and even, 2; tortuous and knotty, 1; tortuous, 2; tortuous and even, 1.

Arcus Senilus.—Male: Seven returns; much, 4; little, 1; absent, 2. *Female:* Nineteen returns; much, 5; little, 8; absent, 6.

Respiration.—Twenty-four returns; average, 24 per minute. Excluding those cases, eleven in number, in which heart or lung disease was returned, or in which the rate of respiration was high, and the condition of the heart and lungs was not mentioned, the average becomes 21–22 per minute. *Regular and Irregular:* Twenty-four returns; regular, 21; irregular, 3.

Teeth.—Forty-two returns; 24 had none, and in 13 the teeth were specified. Amongst the 37 cases there were 144 teeth: upper jaw, 63—incisors, 19; canines, 8; molars, 36: lower jaw, 81—incisors, 23; canines, 13; molars, 45. In five cases the number alone was given. Average (42 cases), 4–5 teeth. In one case they "all came out whole." *Males:* Fourteen returns; 6 had none; average, 4 teeth. *Females:* Twenty-eight returns; 18 had none; average, nearly 5 teeth. Three females had a complete set, and another had 17 teeth; one male had 24, and another 16 teeth.

Artificial Teeth.—Thirty-eight returns; none, 34; yes, 1 (female); many years, 2 (male and female); from 50–90, 1 (female).

Evidences of Failure.—Thirty-five returns; none, 18; failures in 17 cases. *Heart,* 2. In one, "sounds dis-

tinct, no murmur, very irregular, at one minute beating 60–70, and at another double as fast;" in the other, "circulation feeble, frequently sick and faint, as if she were going." *Heart and Lungs*, 3. In one "heart and lung-sounds weak;" in another, "pulse intermits 6 times in minute, impulse weak, slight bronchitis;" in another, "aortic regurgitation, slight bronchitis." *Heart and Urinary Organs*, 3. In one, "loud systolic *bruit* at base, no appreciable interference with circulation, micturition frequent;" in another, "heart-sounds tumultuous and irregular, micturition frequent;" in another, "heart's action slightly irregular, not discernible in pulse, frequent micturition." *Lungs*, 2. In one, "chronic bronchitis;" in the other, "cough for four months." *Brain*, 3. Senile dementia in two cases; in one, "childish for 6 years;" in the third case apoplexy, right hemiplegia, aphasia, and death shortly after. *Brain and Urinary*, 1. "Aphasia for 14 days, incontinence of urine." *Urinary*, 4. One had "some incontinence for 10 years;" in two others, micturition was slow; and in another, "incontinence."

Micturition.—Male: Ten returns; natural, 7; slow, 2; frequent, 1. *Female:* Twenty-three returns; natural, 18; frequent, 2; incontinence, 3; in one case for 10 years.

Cholera among Children.—At a recent meeting of the Vienna College of Physicians Eisenschitz gave the following observations upon Asiatic cholera among children:

He agrees with the opinion of Goldbaum that cholera is a vasomotor paralysis, caused by the specific poison. Except in the case of nursing children, he does not believe that children have a less resistance than adults to infection.

The question of fœtal infection from cholera the observer could not answer; his only post-mortem examination in such cases was negative. Monti belives that a nursing child may become infected through mother's milk; it is more probable that both mother and child are directly infected from the same source.

Artificially nourished children are much more exposed to infection than those who nurse. This is undoubtedly dependent upon the contamination of the foods taken.

The mortality was 55 per cent., which is not greater than among adults; of 7 nursing children all died.

Although prophylactic means were insufficient, no physician or nurse became ill.

Structural changes observed were essentially the same as in adults. The swelling of the solitary glands and of Peyer's patches was more widely extended than with adults. In the typhoid stage of cholera infarcts frequently occurred in the lungs. The glandular alterations were especially pronounced in fulminant cases.

Regarding the prognosis, cases which manifested the usual prodromal symptoms, resulted more favorably than those whose advent was sudden. The predominance of vomiting over diarrhœa was considered a favorable symptom. Temporary improvement the observer did not consider a ground for encouragement, as asphyxia and collapse frequently recurred.

In general, it can be said that the chances of the individual are in proportion to the average rate of mortality.

The duration of the illness was essentially the same with children as with adults.

The algid stage endured in favorable cases from six to thirty-six hours; in fatal cases from nine to fifteen hours.

In cases which recovered the typhoid stage endured six to ten days; with those who died from five to fifteen days. With children less than four years old the algid stage did not exceed twenty-four hours.

The condition, known as typhoid, was characterized by the usual symptoms of typhoid fever, with the addition of persistent vomiting, with dilatation of the stomach, and without singultus: the matter vomited was often acid.

Eisenschitz treated cholera sicca twice. In these cases the stools are often greenish-yellow, instead of rice-water, in appearance; white flecks appear with the stools, and in the intestines abundant rice-water matter is found. Dejections occur during the algid stage without straining, tenesmus is often present during the typhoid stage. Convulsions the observer considered caused by a condition of hydrocephalus, and not peculiar to cholera.

Post-mortem rise of temperature was often seen.

Regarding treatment, the well-known fact that children bear opium badly would prevent the use of a most valuable agent.

In the prodromal period opium is not indicated, and during the early paroxysms it did no good; in the treatment of vomiting hypodermatic injections of one-thirtieth and one-fifteenth of a grain of opium had proved very efficient.

Monti's use of creasote in vomiting and diarrhœa had been repeated with good results, all medication had proved most successful after the high temperature abated.

The careful ingestion of fluids is permitted; warm baths are grateful and very beneficial; the observer had not had good results in the use of stimulants in the early stages.

The treatment of the typhoid stage is tonic and restorative.—*Wiener medizinische Presse*, Dec. 12, 1886.

A Summary of a Table of Oöphorectomies.—Prochownick has collected detailed reports of 22 cases of oöphorectomy, of which 12 operations were made for fibromata and 10 for neuroses.

Of the fibromata 4 diminished in size, 7 disappeared, 1 was extirpated. Among these patients hemorrhage, which had been an indication for the operation, was greatly diminished in 4, ceased in 6, and recurred in 1.

Recovery ensued in 11, in one of whom marked congestion continued for some time. One patient died after extirpation of the tumor from cerebral embolism. Of the 10 patients on whom oöphorectomy was done for neuroses, 3 were not improved, 4 were cured, 3 were improved.—*Archiv für Gynäkologie*, 1886.

An Arterio-venous Aneurism.—Bramann reports the case of a man aged thirty-eight, who had received, a year before he consulted the surgeon, a knife wound in the inner side of the left arm, just underneath the shoulder. The wound healed in the tenth week, but four weeks after its reception a pulsating tumor formed in the left axilla. It increased slowly at first; in the

fourteenth week after the patient was injured, and on his beginning to work, the tumor grew rapidly, and the arm swelled.

On the patient's reception at the Berlin clinic the injured arm was between one and two inches larger than the other; the subcutaneous veins were tortuous, and at the elbow as large as a finger; the skin was moist, cool, and bluish.

In the region of the scar, and under the anterior border of the pectoralis major muscle was a tumor as large as a hen's egg, which was compressible, pulsated with the heart's systole, and in which murmurs were heard.

The tumor extended below to the enlarged brachial vein, in which a second smaller tumor was situated; above, into the axillary vein; the aneurismal murmur was heard very plainly above the clavicle.

The left radial pulse, which was notably weak, became much stronger on compressing the axillary vein, while murmurs and pulsation ceased in the tumor. The same result followed compression of the subclavian artery, and tumor and vein collapsed.

Bergmann, after fruitless efforts at cure by compressing the subclavian artery, operated for the ligation of the axillary vessels and the extirpation of the tumor. The axillary vein appeared obliterated between one and two inches below the tumor; a measurement of blood pressure taken with a Ludwig's mercurial manometer in the central part of a dilated cutaneous vein on the arm gave a pressure of between two and three inches of mercury, while the peripheral portion of the vein showed from three to three and a half inches, which is the normal pressure in the radial and ulnar arteries.

The axillary artery was ligated with a double ligature, the extirpation of the tumor was difficult, and required the sacrifice of the musculo-cutaneous nerve; a degenerated portion of the ulnar nerve was resected, and the cut edges united by catgut.

Recovery followed without accident in forty-five days. Eight months after the operation, the extremity presented the following abnormalities: slight cyanosis of hand and arm, and prominence of subcutaneous veins, with impaired sensation on antithenar region and four or five fingers. Examination of the venous tumor showed a direct communication with the artery measuring one-third of an inch in length and one-sixth of an inch in width. Between this communication and the place where the vein was obliterated, two veins, a superficial and a deep vein, extended. In a table of one hundred and fifty-eight cases of arterio-venous aneurism fifty-six were found to have followed phlebotomy.—*Centralblatt* [illegible]

AN ANTISEPTIC DRESSING.—LUCAS-CHAMPIONNIÈRE gives the following formula:

Iodoform (powdered and sifted),
Powdered quinquinia,
Powdered benzoin,
Powdered carbonate of magnesia, saturated with essence of eucalyptus,
Of each, equal parts.

The powder is applied directly to the wound, and any aseptic absorbent may be used in dressing. After severe operations a fresh dressing will be ordinarily needed in three days; in small wounds eight days may elapse before renewal.—*L'Union Médicale*, Dec. 11, 1886.

INCIPIENT BALDNESS is treated by TILBURY FOX with the following:

R.—Tinct. nucis vom. . . . . ʒiv.
Tinct. cantharides,
Lanoline . . . . . āā ʒijss.
Acid. acetic. . . . . ʒiv.
Aquæ rosæ . . . . . ʒxl.—M.

Sig. Apply with friction.

TREATMENT OF DYSURIA.—MALLEZ recommends the following:

R.—[illegible] . . . ʒj.
[illegible] . . . ʒiss.
Ext. opii,
Ext. aconitii . . . . . āā gr.v.

Ft. pil. 60 in num.

S. [illegible] *de Médecine*, December 12, 1886.

A DISINFECTANT FOR APARTMENTS.—The following will be found useful in the disinfection of houses:

Camphor . . . . . ʒv.
Chloride of lime,
Alcohol,
Water . . . . . āā ʒxij.
Essence of eucalyptus,
Essence of cloves . . . . . āā mlxvj.

Mix; put in a large bottle, and allow to cool.

A few drops, sprinkled upon a napkin, will disinfect a room.—*L'Union Médicale*, December 16, 1886.

THE PURITY OF MID-ATLANTIC AIR.—In the course of an address on the "Action of Microörganisms on Surgical Wounds," Professor F. S. Dennis, of New York, states that during his last trip across the Atlantic he made some experiments to test the purity of the air about 1000 miles from land. He employed capsules of sterilized gelatine, and exposed them for fifteen minutes. One capsule was exposed in the stateroom upon the main deck of the steamer.

Within eighteen hours over 500 points of infection had developed. Two capsules exposed in a similar manner in a cabin on the promenade deck, where the circulation of air was free, showed five or six points of infection each ten days afterward. A capsule exposed over the bow of the ship was found to be entirely uncontaminated. These experiments are on the same line with those of Pasteur and Tyndall upon the mountain air of Switzerland, and, so far as they go, they show the germless condition of mid-oceanic air, and also the need for much more efficient ventilation in the staterooms of even first-class American liners.—*Lancet*, De[illegible]

A NEW PARASITE IN BEEF.—WOLF has found in the intermuscular connective tissue of the flesh of oxen a parasite which is apparently the larval form of an ascaris. It is encysted like trichinæ, but is somewhat larger, and is nearly spherical in shape.—*Fortschritte der Medicin*, December 15, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 8, 1887.

THE CENTENNIAL OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

THE foundation of the College of Physicians one hundred years ago marked an era in the history of the profession of Philadelphia, the climax of which was reached this week in the centennial celebration. The last quarter of the eighteenth century saw in Philadelphia a group of physicians, worthy successors of those earnest men who, as friends and co-religionists, accompanied or followed Penn in the settlement of the province. Many of them had been educated abroad, and appear to have been peculiarly fortunate in their intimate association with the leaders of medical thought in Europe. The close relationship of certain of these men with Fothergill, one of the founders and earliest benefactors of the Medical Society of London, doubtless influenced their action in instituting a similar body in America, for we find that the great Quaker physician took the liveliest interest in the medical affairs of the province, particularly in the foundation of the Pennsylvania Hospital and in the establishment of a medical library. Unquestionably, too, the memory of the pleasant gatherings of the Royal Medical Society of Edinburgh, of which many of them were members, stimulated them to imitate it here. However this may be, to-day, we reap the benefit of their wise forethought, and the successful centennial gathering of this week fitly commemorates their services to the profession.

The President did well in making the chief part of his admirable commemorative address a summary of the medical genealogy of the College. A greater glory than the magnificent building she now possesses, a greater pride than the splendid library of nearly forty thousand volumes, and the choice museum, a surer pledge of permanency, is the roll of names of eminent Fellows who have left their impress on American medicine. The College is local, and the property of a local organization, but John Jones, Morgan, Shippen, Rush, Wistar, Dorsey, Dewees, Barton, Chapman, Wood, Hodge, Meigs, Gross, and many others whose names we honor, belong now, not to Philadelphia alone, not to the College of Physicians, but to the history of the profession of this country. The social force and influence which physicians have always exercised in Philadelphia is not a little peculiar, and there is much truth in the statement that "he is, and always has been, relatively a more broadly important personage here than elsewhere." Certainly, physicians have played a large part in our public as well as private history, and they have "sustained in noble succession the prominence of this city in all that lifts our art and its sister sciences above the common level of applied usefulness."

Probably no other city in the Union, and but few in the old world, could have arranged such a display as greeted the guests of the College at the reception on the evening of the 3d of January. A special attraction was the splendid collection of old portraits of our great masters and worthy Fellows, which indicated how dearly their successors cherish their memory.

It is befitting the city which boasts itself as the "civitas Hippocratica" of America that the library of its chief medical society should be the largest in the country, except that supported by the nation at Washington. The rare treasures, the priceless incunabula displayed in the cases told of the enthusiastic bibliophile, without whose labors the development of the profession in this city would never have reached its present grade. The numerous copies of works by Fellows of the College translated into every language of Europe and into several of the Oriental tongues, which were collected in one case, seem to indicate that, if Philadelphia has lost her commercial supremacy she still leads her rivals in the intellectual race.

Amid the rejoicing and festivities, the conferring of the Associate Fellowship upon nine distinguished men was an appropriate recognition of the debt which the College owes the profession throughout the country; and the ceremonies connected with it were characterized by a grace and dignity worthy of the occasion. In honoring these men the College honored itself and added to a roll already long, the names of earnest and devoted workers.

Knowing the history of the College during the past hundred years we can look to the future with confidence, doubting not that in the century upon which we have entered the progress will be as much beyond our conception as is the realization of to-day beyond the thoughts of the original founders.

NEUROPATHIC JOINT DISEASES.

The occurrence of joint diseases in persons affected with locomotor ataxia has been carefully studied by a number of neurologists, including Charcot, Weir Mitchell, and Westphal, who have attributed such diseases, as well as spontaneous fractures, to tropho-neuroses, and Czerny has recently called attention again to this subject in an interesting paper in the *Archiv für klinische Chirurgie*, Bd. xxxiv. Heft 2, 1886. He points out that, in addition to the weakness of the bones which often exists in ataxia, there is an impairment of the muscular sense, which diminishes the support usually furnished to the bones when under strain, even when they are not especially weak, so that they may give way under the influence of forces which they could resist under ordinary circumstances.

In the inflammatory processes of the joints of ataxic patients the diminished power of resistance in the bones also favors rapid degeneration. Likewise, there is an impairment of sensibility which plays an important part in such processes. This impairment of sensibility first affects the nerves of the deeper structures, so that the skin may even be hyperæsthetic while the parts of the joint are so insensitive that motion is permitted when its influence has become harmful.

The diagnosis of this form of joint disease, according to Czerny, rests upon the occurrence of rapid degeneration in acute cases, and of analgesia, excessive exudation, and great destruction of the parts composing the joint in chronic cases.

Czerny describes six cases, but a careful study of them does not appear to us to establish conclusively the point he desires to make. He admits that the diagnosis of neuropathic joint affections is not easy, and in only two of his cases was degeneration of the spinal cord found, and in four it was only suspected.

There can be no question that disease of the spinal cord may exert an unfavorable influence upon pathological processes in the joints, and it is well to recognize this fact; but it would hardly be safe to assume the existence of such a degeneration merely because an acute joint affection runs a rapid course, or because a chronic joint affection is marked by some insensibility of the deep structures, with great exudation and unusual destruction of the parts involved.

This caution is all the more necessary because, as Czerny says, the importance attributed to this factor may seriously affect the legal rights of a plaintiff, or of a defendant, in a suit for damages for an injury. It might happen, also, in case of a suit, that a surgeon who accepts too unreservedly Czerny's opinions might injure the standing of another who has not learned that when the diagnosis of a neuropathic joint affection is made, the treatment differs somewhat from that which would be proper in one in which no disease of the cord was suspected. In neuropathic joint disease Czerny recommends attempting to secure ankylosis in a good position rather than mobility of the joint. Rest is the chief desideratum before there is much destruction of tissue, and before suppuration becomes dangerous; when the latter occurs, the choice lies between arthrotomy, resection, and amputation.

In conclusion, we may say that, while one is not bound to accept fully Czerny's views of this subject, a proper appreciation of them may lead to the recognition of a factor in joint diseases which must be of great consequence wherever it is present.

TONSILLITIS IN ADOLESCENTS.

Dr. Haig Brown, the medical officer at the Charterhouse School, London, has published a valuable brochure on this subject, which illustrates the importance of carefully studying, in all its aspects, such a common and well-known affection as tonsillitis. The conditions offered by a large public school are particularly favorable for observation, and among the large number of boys between the ages of twelve and nineteen, Dr. Brown found ample material upon which to base some very interesting remarks. The greater liability to the affection during the evolution of the generative organs is illustrated by the fact that 105 of 127 consecutive cases were between fourteen and seventeen years of age. The association of tonsillitis with rheumatism is well recognized, but we do not remember seeing the relationship more forcibly shown than by this writer. Of the 127 cases, from 119 trustworthy information was obtained as to the presence or absence of a rheumatic condition, and of these, 76 gave some history of rheumatism, either personal or in members of their immediate family. 20 of the cases presented what is known as the "rheumatic aspect," a combination of dark hair, a fair skin, red cheeks, and thick lips.

The disease is regarded as a specific disorder, to which septic conditions specially predispose. Some very interesting facts are given illustrating the prevalence of the affection in houses exposed to sewer emanations. The diminished power to resist disease is so produced, assisted by the deteriorating influences of puberty, a damp climate, and rheumatism, and is the usual predisposing reason for attacks of tonsillitis, which are probably determined by cold or contagion. Several very instructive instances are given in illustration of the highly contagious nature of follicular tonsillitis.

By far the most valuable part of these observations relate to the cardiac complications of the disease. Here and there we find a writer who refers to ton-

sillitis as a possible cause of endocarditis, but, so far as we know, no one has before so clearly brought out this point. A careful examination of the heart was made in 360 cases, of which 14 had previously suffered from rheumatic fever, and were excluded. Of the remaining 345, in 33, or 9.6 per cent., a cardiac murmur was developed. Of these cases, 8 were systolic basic murmurs heard over the pulmonary artery, and all disappeared in four weeks under treatment. 18 were systolic apex murmurs, which developed within three days of the commencement; 14 of these were solitary and of these, 10 disappeared within four weeks; 4 persisted for more than six months; 2 were pericardial friction murmurs, which did not last beyond the seventh day. 1 case had pericardial friction with systolic apex and diastolic basic murmurs. 4 were combined systolic and presystolic bruits. Briefly summarized, of the 345 cases, 8 had endocardial lesions which terminated in chronic valve disease, 3 had pericarditis, 10 had the physical signs of mitral regurgitation which disappeared, and 8 had functional murmurs due to anæmia. Doubtless, we have in this complication of so common a disease as tonsillitis an explanation of certain of the cardiac cases we meet in which there is no history of rheumatism, chorea, or other affection liable to be accompanied with endocarditis. A knowledge of its occurrence should make us watch the heart in this affection, and carefully guard the patient during convalescence should a murmur develop.

THE RELATION OF PHTHISIS TO DISEASE OF THE OVARIES.

Attention has recently been called by Fenwick, in *The Lancet*, for October 16 and 23, 1886, to a possible relation between diseases of the ovaries and diseases of the lungs, which he formulates as follows: Ovarian cystic disease arises in many cases because the patient has a hereditary tendency to degenerative changes, or, in other words, belongs to a phthisical family. He has examined with care the literature of disease of the ovaries, and has not found that any observer has hitherto suggested or proved any family predisposition in such cases. From an analysis, however, of the records of the London Hospital for Women, from 1882 up to the present time, and of two cases occurring in intimate friends of his, with a few isolated cases reported by different authors, in all a little over 150 cases, he has come to the conclusion stated above. He could find reliable data as to the family history in only 60 of these cases, and in 32 of these families phthisis had existed. Other cases furnished some corroborative evidences of the influence of a tendency to phthisis in the subjects of disease of the ovary, so that he includes no less than 42 out of 60 cases in this category.

Fenwick supports his opinion by the fact that phthisical men are liable to disease of the testicle, the analogue of the ovary. He also attaches importance to the fact that caries of the teeth, which is common in phthisical subjects, is also found in a number of patients with cystic disease of the ovary. He believes that cystic degeneration of the ovaries is, like phthisis, frequently hereditary.

One of the most important tests of Fenwick's theory would be to ascertain whether or not women with disease of the ovaries are prone to manifest well-established evidences of phthisis. He produces but little testimony on this point. Sir Spencer Wells, he says, notes incidentally that out of his first 300 cases, 3 died of phthisis within the first two years after operation.

Fenwick does not claim anything more for his theory than that it appears probable. In this we entirely agree with him, and, although we feel that he may be making the mistake of taking coincidence for causal relation, we think he has made out a sufficiently strong *prima facie* case to warrant his appeal to those who shall in the future report cases of cystic disease of the ovaries, to narrate as fully as possible their family history, that more definite opinions may be formed as to the relation to it of a phthisical diathesis.

INTRACRANIAL PRESSURE.

In discussing compression of the brain in The Medical News for November 14, 1885, we called attention to some interesting investigations in regard to intracranial pressure which have a decided practical value in considering injuries to the contents of the skull. More recently, in the *Deutsche medicinische Wochenschrift*, of October 28, 1886, there is a report of a communication on this subject, made by Knoll, of Prague, to the fifty-ninth meeting of German Naturalists and Physicians. In it he described some experiments in which he introduced a canula through the atlo-occipital ligament into the fourth ventricle of the brain in certain animals. By artificial interference with the respiration, he caused variations in the blood-pressure which were accompanied by a corresponding increase in the pressure of the cerebral fluid. But he observed that when the blood pressure was lowered by bleeding, the pressure of the cerebral fluid diminished more slowly than did that of the blood, so that the brain did not become anæmic as rapidly as any other organ of the body.

If this be proved by further observations and experiments, it will establish a very comforting doctrine. As yet, however, we cannot accept it without reserve, since the details of Knoll's experiments are not at hand, and it is impossible to say how far his deductions apply to man. One important element

in the case, and one which supports his opinion—although he has not called attention to it—is the fact that the contents of the skull are surrounded by an unyielding wall, so that they cannot collapse as readily as most of the other organs of the body, or admit of the drainage of their contained blood, since this would tend to create a vacuum. It would be interesting to study in this connection the condition of the bloodvessels in the long bones after venesection, so as to ascertain whether or not they too retain a proportionately large quantity of blood when the vessels of soft organs become anæmic.

However this may be, it must be remembered that anæmia of the brain is not the only condition which may interrupt consciousness, or even end life. Mere stasis of the cerebral circulation may produce either of these results, without any alteration in the absolute or relative quantity of blood in the skull. For this reason we must not mistake the significance of Knoll's observations, however interesting they may be, or however important it may be to take them into consideration in studying injuries of the brain.

The measles epidemic in New York, it is gratifying to be assured, is on the wane, though it is still doing sad work in the tenement-house district, the last week showing 468 cases and 63 deaths. At the same time, diphtheria claimed 40 deaths and 104 cases, and scarlet fever 30 cases and 3 deaths. Measles is quite as prevalent in Jersey City and Williamsburg as here.

On Wednesday, December 29, 1886, the Training School for Nurses at the Hospital of the University of Pennsylvania was opened. A lecture upon the treatment of fevers was given by the Provost, and a large and interested audience listened to his remarks, and afterward inspected the commodious and tasteful home of the nurses. In the plan of the enterprise, the details of the administration of the school, and the completeness of its equipment it reflects honor upon the wisdom and liberality of those who established it.

A legal case of considerable importance to physicians has just reached a final decision. Dr. Alfred S. Purdy and his son, of New York City, determined that Angelina M. Brown was suffering from smallpox in November, 1879. They reported their conclusion to the New York Municipal Board of Health, and the woman was taken to the Smallpox Hospital. There it was discovered that she had not the disease. She sued the Drs. Purdy for $5000 damages, and a jury in the Superior Court recently awarded her damages. The Superior Court, General Term, decided that the complaint should have been dismissed, as there was a reasonable doubt as to the character of the disease in the beginning, and as it was the duty of the physicians to report the case to the health officers, who then assumed the responsibility of taking her to the hospital.

At the Long Island College Hospital the chair of Medicine left vacant by the death of Prof. S. G. Armor has been filled by the election thereto of Dr. Frank E. West, an alumnus of that school, of the class of 1876. Prof. West had been for many years the favorite assistant, as well as the intimate friend, of the late eminent teacher, and his promotion to the full professorship has in it the merit of a civil service appointment.

The ambulance service at the Long Island College Hospital, which has an eventful and useful record, is temporarily under a cloud by reason of a disagreement between the Hospital authorities and the Board of Health, in reference to the selection of ambulance surgeons. The present indications are that the time is coming when the city of Brooklyn will cease to own and run ambulances, and when the various hospitals will each maintain a station of its own, receiving a certain monthly payment from the city for their services to the public.

Smallpox has prevailed to some extent in Brooklyn this winter, the disease being imported in the person of a Polish immigrant; a goodly corps of special vaccinators has been diligently at work in efforts to circumscribe the outbreak. The disease has not spread very widely, although in one house as many as eight deaths thereby have been reported.

REVIEWS.

[illegible]: A text-book for students of medicine. By Gerald F. Yeo, M.D., F.R.C.S. Second American edition. Philadelphia: P. Blakiston, Son & Co., 1886.

A [illegible] Human Histology, including Histology and Microscopical Anatomy; with special reference to the requirements of Practical [illegible]. Second American, translated from the fifth German Edition, with additions by William Stirling, M.D., Sc.D. Philadelphia: P. Blakiston, Son & Co., 1886.

It is difficult, and perhaps impossible, to name any single text-book which shall properly fulfil the needs of the medical student in his two years study of physiology. At the very beginning of his course, while he is yet helplessly floundering in the waves of new words and new thoughts, it is almost cruel to place in his hands that best of English text-books, Foster's *Physiology*, and bid him comprehend the opening chapter on the blood. His knowledge of organic chemistry, and

the types of proteids is, to say the least, sufficiently slight to render the descriptions of fibrinogen and fibrinoplastin eminently depressing. Yeo's manual is, perhaps, of all the smaller works the one best adapted to the needs of the typical first year student. So far as functions so marvellously interdependent as those of the human frame may be treated in natural logical sequence, so far is that sequence observed. The study of the functional systems is preceded by an admirably arranged introductory statement of the vital phenomena in general. In spite of the fact that gratuitous difficulties are removed from the path of the student, the book is sufficiently advanced in character to demand close study.

As a supplement to this book, for use in the second year of medical study, and, indeed, for reference in actual practice, Landois's text-book, a work at once compact and encyclopedic, is unquestionably to be commended.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

CENTENNIAL ANNIVERSARY.

Commemorative Meeting held January 5, 1887.

THE PRESIDENT, S. WEIR MITCHELL, M.D., IN THE CHAIR.

DR. ALFRED STILLÉ related the following

REMINISCENCES OF THE COLLEGE.

He said: We who form a portion of the continuous life of the College, links in the chain of its existence, are corporately, if not corporeally, one hundred years old to-day. But what is a century in the life of an institution? The years that carry a man to his dotage and decay are but the infancy, the childhood, or the youth of the nation, the community, the society, whose longevity may be reckoned, not by years or generations, but by centuries. It is less by the duration of a man's life than by his vigor that his capacity for continued existence must be determined, and this can be gauged only by his achievements. The ability to do must be estimated by what has been done.

The infancy of our College was a precocious one. Its corporate existence began with an infusion of learning and talent among its members out of all proportion to the age of the institution. Many of its original Fellows had been nurtured in colonial times when a trans-Atlantic education was felt to be the necessary complement of the rude, scanty, and disjointed instruction attainable at home. But from the War of Independence the European supplement was less frequently added to the gains of domestic training, and for more years than it is pleasant to number, the chief illumination within the College was furnished by the twilight left by the great luminaries that had sunk beneath the horizon. During the first thirty or forty years of this century, it seemed as if the old scholarly life of the 18th century had ebbed away from it, as it had from the whole medical profession, and its resurrection dates from nearly the same period that witnessed the revival of science and letters in Europe, the French revolution of 1830. During the next decade a number of young American physicians brought from Europe to our greater cities the methods of study and the knowledge they had gained abroad, and it is from that beginning, so insignificant in its mass, that medicine in this country received its first impulse in modern, as it had in remoter times; by it was it leavened, and raised to its present degree of dignity and usefulness.

The College of Physicians at that time was mainly composed of the elders of the profession, who instinctively clung to old and familiar paths, and who resented the intrusion of new ideas as almost impertinent. Age and station then had a much more preponderating influence than at the present day, and the young were as timid in expressing even their well-considered opinions, as the old were prompt to resent and frown down all dissidence and contradiction. There was also a special lack of harmony, if not a positive antipathy and antagonism, between the physicians who had been trained abroad and their pupils, on the one hand, and their elders, on the other hand, who kept to the ancient paths, and were content to plod therein, and who set more value by doctrinal differences and the logomachy of systems, than by the simple, unbiassed observation and comparison of clinical and experimental facts.

As something like this do I recall the aspect of our little province in the medical world when I first beheld it in 1842, awed, perhaps, by its luminaries, who, however, did not eclipse the greater ones that my eyes had grown accustomed to abroad.

Conservatism has always been our dominating spirit, as becomes all institutions that aim at permanency. It has distinguished not only its scientific and ethical features, but also the management of its material interests. As it felt that the latter were too valuable to be hazarded by the vulgarization of its Fellowship or by incautious legislation, so has it always maintained that the physician's office possessed a certain sacerdotal sanctity, and that its special constitution and its relations to the public required specific rules, as much as the commonwealth requires specific laws to enforce the commands of the second table of the decalogue. In 1843 the College framed the Code of Ethics which a few years afterward was substantially adopted by the American Medical Association. Only of late years, and since its moral bonds have become irksome to some who perhaps failed to distinguish between liberty and license, has the soundness of this synopsis of professional right and duties been called in question.

In 1845 the College hesitated to send delegates to the Convention which formed the American Medical Association upon the ground that the chief object of the Convention was not likely to be gained by the means proposed. And although it did afterward take part in this movement, and even an influential one, history has demonstrated the clearness of its foresight by proving the incapacity of medical societies, by the mere force of authority, to lift themselves or the medical profession out of the ruts of routine and the mire of ignorance.

Dr. Stillé then adduced the evidence of sympathetic interest the College has always shown in whatever concerned the progress and interests of medicine and the welfare of the community. It has never been governed by narrow and selfish motives, but has always given ungrudgingly of its wisdom and knowledge for the pro-

motion of every good work. It has lived up to its motto, "*Non sibi sed toti.*"

It would offend the susceptibility of some who are still among us, if I were to speak of their special acts of liberality, but I may mention two or three which, however prompted, were not carried out by those of our own household. I allude particularly to the silver service; the "Loving Cup;" the copy of Rembrandt's famous picture of "The School of Anatomy," now upon its way from Europe; and the elegant and classical chimney-piece that adorns the "Mütter Museum."

I turn now, in the last place, to give you a short history of the College library. Forty-one years ago on one side of the President's chair there stood a book-case of moderate size. It was painted black, I think, and through its glazed doors could be dimly seen a few hundred volumes varying in size from folios and quartos to humbler types, and all by their musty and dingy bindings proclaiming their long disuse. Among them was a fine edition of Galen, presented by the great Italian Morgagni to his eminent American friend, Dr. John Morgan, with a humorous suggestion of relationship prompted by the similarity of their names.

The ancient receptacle I have mentioned irresistibly suggested the chamber of an Egyptian tomb, where the dry and blackened mummies of the dead repose unchanged for untold ages. If the doors of it were ever opened it must have exhaled a sepulchral odor. But we know that even in the forbidding relics of the ancient dead grain has been found which, under the influence of sunlight and moisture, has germinated and renewed the crops of many centuries ago. So these dry and lifeless tomes, removed to a brighter and livelier atmosphere, and tended by a succession of intelligent and industrious cultivators, have formed the seed of the great harvest that this day surrounds us.

In 1843 there was a sinecure officer in the College, called Librarian. He made annual reports, and in the year mentioned his report was brief and expressive—"The library is seldom used." In 1844 the library committee reported that owing to the "present limited state of the collection," it was not expedient to open it more than twice a month! But in the succeeding year the acquisition of Dr. Otto's library seems to have borne fruit, for it was followed by gifts from various Fellows, among whom Drs. Wood, Hays, Bond, and Moore may be mentioned, and at the same time the College acquired the library of the deceased Medical Society of Philadelphia. In 1849 nearly a score of medical journals were received in exchange for the Transactions of the College, and thenceforward at nearly every stated meeting gifts of books were announced. But even as late as 1855 the library contained only 1700 volumes.

But the most important epoch in the history of the library was the founding of the Lewis Library in 1864, which at once added to it more than 2500 volumes of the choicest works in the finest condition, so that in 1866 the librarian was able to report a total of 9513 volumes. Thenceforth "crescit eundo" literally described the progress of the library.

In this partial retrospect of the history of the College during the last forty years, one can hardly fail to note that in it, as in political and social, and, indeed, every history, progress has depended upon individuals. The hour must come, and the man must arise who, by his voice or his example, stimulates other men to vigorous and fruitful action. As in its infancy the great name of Rush dominated the College, through his inventive genious and foresight, so in its later history George Bacon Wood ruled it by his wisdom and liberality; another has made illustrious his living name by opening a rich mine of intellectual wealth for all seekers after knowledge; and still another is distinguished for his liberality in promoting the social, artistic, and literary tastes of his fellow members. All, by their example, have so warmed the enthusiasm and quickened the sympathies of the Fellows, that this commodious building, this precious scientific museum, and this noble library have sprung into existence in the brief space of a single generation.

Let us hope that so fair a flower of science shall not languish through indifference, neglect, or indirection, and that at the end of another century our posterity shall be able to speak of us with unstinted praise, and with as sincere gratitude as we now feel toward those who prepared the way for this goodly habitation and temple dedicated to the service of humanity.

The President then conferred the honor of

ASSOCIATE FELLOWSHIP

on the following gentlemen, and in the following terms:

Henry Pickering Bowditch, M.D., Professor of Physiology in Harvard University; physiologist and statistician.

David Williams Cheever, M.D., Professor of Surgery in Harvard University; a bold and thoughtful surgeon; a teacher with the tongue and the pen.

William H. Draper, M.D., Professor of Clinical Medicine in the College of Physicians and Surgeons, of New York; the trusted consultant; the clinical teacher; the physician and writer.

Robert Palmer Howard, M.D., Professor of Medicine in McGill University, Montreal; clinical investigator; writer, and teacher.

Hunter McGuire, M.D., of Richmond; a surgeon distinguished in war and in peace; teacher of surgery; President of the American Surgical Association.

George Cheyne Shattuck, M.D., LL.D., of Boston; clinical investigator; eloquent teacher; generous benefactor of medical and secular education.

Nicholas Senn, M.D., Professor of Surgery in the College of Physicians and Surgeons of Chicago; investigator in surgical pathology.

Theodore Gaillard Thomas, M.D., Clinical Professor of the Diseases of Women in the College of Physicians and Surgeons, of New York; medical author; teacher; clinical investigator.

James T. Whittaker, M.D., Professor of Medicine in the Medical College of Ohio; clinical teacher; physician, and writer.

Dr. J. M. Da Costa then made an

ADDRESS OF WELCOME.

He said: To me has been assigned the agreeable duty, on an occasion so interesting, of welcoming, on behalf of the College, these masters of our art as Associate Fellows. Our Institution has put on its holiday dress to celebrate the one hundredth anniversary of its foundation, and one of the most pleasing features of the commemorative gathering is the admission of a number of men of

distinction as Associates. In this, the College is but carrying out the implied wish of its incorporators. It is calling those to it who have assisted "in the prosecution and advancement of useful knowledge for the benefit of their country and of mankind."

What thoughts would have filled the minds of those worthies who founded this College could they be with us now. What rejoicing at the success of their literary and scientific undertaking would these old physicians of Philadelphia have indulged in. What pride would they, patriots formed in the stern school of sacrifice and suffering of a long war, have taken in the fact that from so many parts of their country, grown in these hundred years from sparsely inhabited stretches of land into a teeming, powerful empire,—from cities they were familiar with, but in whose present magnificent proportions they would find themselves wondering strangers; from wildernesses they scarcely knew of even by name, now thriving, populous States,—had come, with a promptitude and rapidity which progress in applied science has alone made possible, those "viri docti et medicinæ periti," they would themselves have delighted in welcoming.

Every age has its impress and its tendencies. The queue, the knee-breeches, the gold-headed cane, the stately manner, the reverence for old wisdom, the classical canon were their emblems, and bespoke that which they declared to be one of the objects of this College—"to cultivate order and uniformity in the practice of physic." Though not blind to your other qualities, it would have been for any near approach to their standard of order and learning, that they would have mainly esteemed you. Our age is an age of zealous investigation and active change. Newly elected Associate Fellows, we find represented in your ranks what in these days we chiefly honor in our many-sided profession. We find learning and order, but we also find love of research, originality, boldness; we note you quick of eye, fertile of resource, independent of thought. And if we have singled you out on this occasion, it is because you are the type we delight in, the true children of our time and tendencies.

Associates, in joining you to us to-day, we bestow on you all this College has to bestow. It gives you full share in all that a century of learning, of culture, of pure aims, of renown, of high tone, most zealously guarded, has done to make it famed and respected. On its part, it takes a mortgage on your past acquisitions, as well as lays claim to a portion of the results of your future work. And when some fresh, thoughtful deduction in practical medicine becomes the theme of every pen; some new, life-saving operation is everywhere discussed; some clear monograph of exhaustive research and wide grasp is by everyone lauded; some ingenious application of physiological experimentation laid before the world; when we hear of a celebrated treatise of a great practical master being translated into yet more tongues,—we shall feel the pride of possession in our Associate Fellow, and rejoicing in his success, claim him, for the College, as among our own. These are the feelings we have toward you, and we now greet and welcome you as sons of this old Institution with all the love of brotherly affection.

The President then adjourned the meeting, and on behalf of the College invited the Fellows to luncheon in the old Museum Room.

THE DINNER.

In the evening the Fellows dined together in the Assembly Room of the Union League. After the cloth had been removed, the President presented the toast of the "Memory of the Founders of the College," which was drunk in silence. Subsequently Dr. Henry Hartshorne read some appropriate verses. The President then offered the toast of "The Fellows of the College," and asked the company to pledge each other in the loving cup, which was passed round. Dr. D. Hayes Agnew responded to this toast.

The toast of the "Associate Fellows" was proposed, and replied to by Dr. T. Gaillard Thomas, of New York. Dr. Pepper then responded to the toast of the "Physician," Dr. Ashhurst, to the "Surgeon," Dr. Parvin, to the "Obstetrician," and Dr. John S. Billings, to the "Medical Societies of America."

The formal toasts of the evening having been concluded, Dr. George C. Shattuck rose and claimed the privilege of proposing a toast and asked the company to drink to the health of the College of Physicians, and to its prosperity and long life. The toast was received with enthusiasm and the President acknowledged the compliment in a few brief remarks.

Dr. Weir Mitchell then read the following

COMMEMORATIVE VERSES.

A Doctor's century dead and gone!
Good-night,—[illegible one hundred years]
To all the memories they bear
Of honest help for pains or tears.

Good-night! a century's good night,
To such as for our noble guild
Stood firm when death was in the air
And fear all meaner bosoms filled.

To them that like St. Christopher,
When north and south were sad with graves,
Bore the true Christ of charity
Across the battles' crimson waves.

Good-night to all that shining line,
—Our peerage—yea, our lords of thought,
Their blazonry unspotted lives
Which all the ways of honor taught.

A gentler word,—as proud a thought,—
For those who won no larger prize
Than humble days well lived can win
From thankful hearts and weeping eyes.

Too grave my song,—a lighter mood
Shall bid us scan our honored roll,
For jolly jesters gay and good,
Who healed the flesh and charmed the soul,

[illegible]
[illegible]
Then bore them [illegible]
And slept, [illegible] heard the night-be[illegible]

Our century's dead: God rest his soul!
[illegible]
Without a "post," without a dose,
He's off on time's old rattling hearse

[illegible]

Our new-born century, pert and proud,
Like some young doctor fresh from college,
Disturbs our prudent age with doubts
And misty might of foggy knowledge.

Ah, but to come again and share
The gains his calmer days shall store,
For them that in a hundred years
Shall see our "science grown to more."

Perchance as ghosts consultant we
May stand beside some fleshly Fellow,
And marvel what on earth he means,
When this new century's old and mellow.

Take, then, the thought—that wisdom fades,
That knowledge dies of newer truth,
That only duty simply done
Walks always with the step of youth.

A grander morning floods our skies
With higher aims, and larger light,
Give welcome to the century new,
And to the past a glad good-night—!

The recital of these verses which elicited prolonged applause, concluded the festivities of the evening.

The feature of the Dinner Menu, which was in book form, was the interspersion of apposite quotations from Shakespeare. On the cover was engraved the seal of the College, and below this was inscribed—

"Feasts so solemn and so rare
Since, seldom coming, in the long years set,
Like stones of worth they thinly placed are,
Or captain jewels in carcanet."

On the reverse was the accompanying medallion portrait of the first President of the College, Dr. John Redman.

"He [illegible]
[illegible]
[illegible]

A RECEPTION

was held in the Hall of the College on Monday evening, January 3d. The building was beautifully decorated with flowers and the walls were adorned by a very large and interesting collection of portraits of deceased Fellows of the College and others.

Among the guests present from a distance were Drs. Fordyce Barker, of New York; John S. Billings, of Washington; Traill Green, of Easton; A. M. Pollock, of Pittsburg; Nicholas Senn, of Milwaukee; Hunter McGuire, of Richmond; James T. Whittaker, of Cincinnati; H. P. Bowditch, of Boston; T. Gaillard Thomas, of New York; W. H. Draper, of New York; D. W. Cheever, of Boston; George C. Shattuck, of Boston; R. Palmer Howard, of Montreal; Robert T. Edes, of Washington; R. F. Weir, of New York; J. R. Chadwick, of Boston; A. Jacobi, of New York; George M. Sternberg, U. S. A.; C. C. Lee, of New York; F. Lange, of New York; F. Donaldson, of Baltimore; E. Darwin Hudson, of New York; Ezra M. Hunt, of Trenton; R. F. MacDonald, of Montreal; A. H. Halberstadt, of Pottsville.

NEW YORK SURGICAL SOCIETY.

[illegible]

Dr. Charles T. Poore read a paper on the

[illegible]

The majority of infants with this deformity are, and can be cured by mechanical treatment, but there are a certain number of persons, who, either from the marked degree of the deformity, neglect, or inefficient treatment, are unable to walk on the plantar surface of their feet, and in whom locomotion is labored and painful. Even in children it is sometimes impossible to hold the foot in a proper position without the aid of an apparatus after years of careful treatment. With the brace applied they are able to walk on the plantar surface of their feet, but as soon as it is removed the anterior portion of the foot reverts to its abnormal position.

The cause of this failure to relieve the deformity is not clearly understood, or, if acknowledged, is not appreciated. In order to understand the cause of this inability to hold the anterior portion of the foot in a proper position, and, when an operation is called for, to judge of the best means of correcting the deformity, a consideration of the anatomy of congenital equinovarus is necessary.

Dr. Poore has examined the bones taken from a child eight months of age, who exhibited this deformity.

The patient had been under treatment for some months, and, at the time of death, the anterior segment of the foot had been brought into its normal position, and held there as long as the splint was on, but on its removal immediately reverted to its abnormal position. The tendo Achillis had been divided.

In comparing these bones with those taken from a child of eight months the following points of difference are noted. The angle at which the neck of the astragalus is set upon its body in the bone from the deformed foot is 55 degrees, while that of the normal bone is 28 degrees; the external surface of the neck of the abnormal is much longer than that of the normal bone—the articulating surface of the head is much smaller in the

former than in the latter, The anterior articulating surface of the os calcis is directed forward and inward in the bone from the deformed foot, while in the normal it is directly forward. Its anterior portion is curved outward in the deformed foot, but is straight in the one from the normal foot.

It seems established that the obliquity of the neck of the astragalus is a normal condition in infants at term; that in varus, as a rule, the amount of this obliquity is increased; and that in the adult bone the neck is set upon the body of the bone at a mean angle of 10.65 degrees. That in varus the anterior portion of the os calcis is curved with its convexity looking outward, and that its anterior articulating surface is directed forward and inward. It is evident, then, that during growth the axis of the neck of the astragalus, in the normal foot, changes from an angle of 38 degrees to one of 10.65 degrees, with that of the longitudinal axis of the body.

The pathological changes found in the majority of cases of congenital talipes equino-varus may be described as an exaggerated obliquity of the neck of the astragalus, and a curvature of the anterior portion of the os calcis, together with its elongation; and that the head of the astragalus is held in its abnormal position by short ligaments; that the scaphoid is carried upward and forward by the head of the astragalus, and held there by the abnormal condition of the ligaments; that the muscles have nothing to do with its causation, nor do they act as much of an obstacle to the restitution of the foot. Exception should, however, be made to muscles entering into the formation of the tendo Achillis.

It should be stated that in one dissection reported by Messrs. Parker and Shattuck of congenital equino-varus, the obliquity of the neck was only 31 degrees, being less than in the normal bone.

If the foregoing facts have been correctly interpreted, the indications for the treatment of congenital equino-varus seem simple. The object of mechanical treatment must be to stretch the ligaments upon the inner side of the foot, which hold the scaphoid and head of the astragalus in their abnormal position, so that the obliquity of the astragalus may undergo the diminution incident to normal growth, or, in other words, assume the form of the adult astragalus. There is still another element, in some cases at least, which prevents a perfect restitution and that is the elongation of the os calcis; even should the deformity of the astragalus be entirely overcome, the outer border of the foot would be longer then its inner, and thus continually tend to force its unsupported anterior segment inward.

In those cases which have resisted all known methods of mechanical treatment, the question arises, What operation is the best to restore the foot to a useful position?

The only operation that has of late years commended itself to surgeons, is a cuneiform osteotomy or resection of the tarsal bones in front of Chopart's joint; all others have failed to accomplish the end for which they were performed and have been abandoned.

Tenotomy of the ligaments commends itself as one from which good results may be expected in infants, because it attacks the structure which is the chief obstacle to the normal development of the astragalus, but it has no influence on the curvature of the os calcis, and this, it would seem, is the cause of imperfect restitution in other more promising cases.

In looking at a dissection of a foot affected with the deformity under consideration, the following points suggest themselves:

1st. That the inability to correct the deformity was due to changes taking place in the astragalus and os calcis.

2d. That in order to bring the anterior portion of the foot into its normal position, the curvature in the os calcis must be renewed and the neck of the astragalus shortened, so as to allow its head to point in the normal direction and thus carry with it the scaphoid and other tarsal bones.

To accomplish this the following operation was performed: An incision was made from a point one and a half inches in front of the tendo Achillis in the outer aspect of the foot forward to the middle of the cuboid bone, and down to the tendons of the peroneus longus and brevis; these should be raised or pushed out of the way. Another incision beginning from the middle of the first and corresponding to the neck of the astragalus was made directly upward. The tissues were then raised from the bones, and the periosteum incised over that part of the os calcis from which it was desired to remove the wedge. With a chisel a V-shaped piece of bone was taken away base outward, and its apex extending to its inner border; a wedge was then removed from the neck of the astragalus of such a shape as to allow the anterior portion of the foot to be brought outward and upward.

The periosteum was united with catgut and the skin with several wire sutures, because the latter hold longer and give better support. An aperture was left posteriorly for the insertion of a drainage tube, a plaster-of-Paris bandage applied extending from the toes to above the knee, and the foot placed in a corrected position. The wound was dressed with iodoform and gauze.

The size of the V-shaped interval left after the removal of the wedge of bone should be sufficient to allow the anterior portion of the foot to be placed in a proper position without any tension on the tissues on its inner aspect. I think that a subcutaneous division of the ligaments on the inner border of the foot, where they are tense, would facilitate the correction.

The dressing should be as light as possible, not bulky, otherwise it will be found difficult to apply the plaster-of-Paris bandage firmly. A little over-correction does no harm.

The advantages claimed for this operation over that of removing a wedge from in front of the medio-tarsal joint are:

First. It is anatomically and mechanically correct.

Secondly. Less amount of bone has to be removed, because the operation is performed nearer the apex of a triangle.

Thirdly. No joint is entered, and consequently the foot is left in a more normal condition.

Fourthly. It does not practically shorten the foot in front of the ankle-joint.

The class of cases suitable for this operation are:

First. Those patients who have reached the age of five or six years with the deformity unrelieved, and who have walked on their feet, and in whom the parts are rigid and the deformity marked.

Secondly. Those cases in which, although the anterior portion of the foot can be brought into position, yet

require an apparatus to retain the foot in its normal position after years of careful treatment.

Thirdly. Those cases in which the obstacle to restitution is due to elongation of the os calcis; perhaps in these patients the removal of a small wedge from that bone would accomplish the object.

Case I.—W. S., ten years of age, was admitted into St. Mary's Hospital, September, 1885, with congenital talipes equino-varus of the left foot. The deformity had never been treated. He walks on the outer aspect of his foot. The parts are very rigid, and with the hand no change can be made in the position of the anterior portion of the foot. There is no motion at the ankle-joint.

In October, the tendo Achillis was divided, and Bradford's instrument for forcibly rectifying club-foot used, but no impression could be made in the position of the foot. In November, another attempt was made with the same instrument, but with no better success.

On January 14, 1886, I performed the operation advocated in this paper, and brought the anterior segment of the foot into a straight line. There was considerable oozing of blood for a day, so that the dressings had to be changed, and in a week some slight suppuration. During the treatment he had an attack of scarlet fever. The wound all closed within a month, but he was not allowed to use his foot for eight weeks. At date of discharge from the hospital he was able to walk well with his foot flat on the floor. There was but little motion at the ankle-joint. The line of the inner and outer border of the foot is perfect, with not the slightest tendency to inversion.

Case II.—A. S., eight years of age, was admitted into the hospital in November, 1885, with double congenital talipes equino-varus. His tendons have been cut and he has been under mechanical treatment for years, but with no benefit.

The os calcis is in its normal position, but the anterior portion of the foot is turned at a right angle to the os calcis. Three attempts have been made to correct the deformity with Bradford's instrument, but without making any impression on the position of the foot.

December 21, 1885. A wedge was removed from the os calcis and neck of the astragalus in the same manner as mentioned above.

Wound was all closed in a few weeks. Temperature never over 100°.

February 6. The same operation was performed upon the right foot.

At date of discharge patient was able to walk with the sole of the foot flat on the floor. The patient has always had some paresis of the extremities, so that he has never had good use of his limbs. He walked at time of discharge quite well. But there is a tendency of the whole foot to roll inward. I do not think that the correction was as perfect as in the first case.

Case III.—W. J. C., aged fourteen, has been under treatment at the hospital at times for several years. She has had a congenital talipes equino-varus of left foot, which has been corrected, so that the anterior portion of the foot can be brought into its normal position with the hand, but immediately on removal of the support turns somewhat inward. She has worn a brace for several years; with it she gets along pretty well, but without it the foot is almost useless.

February 28, 1886. A V-shaped piece of bone was removed from the os calcis and neck of the astragalus, and the anterior portion of the foot placed in a straight position. Plaster-of-Paris splint and dressings of gauze and iodoform, as in the other cases, were used. Owing to illness, I did not see the patient again for a week. She then had a high fever, the foot was swollen, and the wound looked blue and sloughy. The splint was removed and the wound cleansed. The fever continued, and she died on the twelfth day of septicæmia.

DR. STIMSON asked whether in the latter case it were possible to raise the foot in dorsal flexion inside of a right angle.

DR. POORE replied that he thought there was limited motion in the ankle-joint.

DR. STIMSON remarked that the basis of Bœckel's operation was removal of the astragalus because that motion was interfered with, and a limp was the necessary consequence.

DR. POORE said that he did not see how that could be, as he was certain that some of the cases in which cuneiform osteotomy had been performed had normal motion at that joint. Another objection to the cuneiform osteotomy was made, viz., that it interfered with the growth of the foot; cases had been reported in which good results had been secured at first, but, as the child grew, the foot failed to grow in proportion.

He thought it was probably because the operation had been performed anterior to Chopart's joint, and thus an inch and a half had been removed from the foot. He said it could not be known how much shorter the foot would be on reaching maturity, but he thought it better than the cuneiform operation in front of Chopart's joint.

DR. BRIDDON presented the stomach and wounded portion of intestine of the following case of

LAPAROTOMY FOR PISTOL-SHOT WOUND OF STOMACH; PERFORATIONS OF SMALL INTESTINE NOT RECOGNIZED DURING LIFE; DEATH.

Lizzie W., a patient brought to the Presbyterian Hospital, at 6.30 P. M., November 20, 1886, during the service of Dr. Briddon. She reported that she accidentally shot herself while holding in her right hand a revolver, which she supposed was unloaded. She was dressing at the time, the ball passing simply through her underclothing. The shooting occurred about two hours before admission. On admission patient was not in collapse. Her pulse was 80, full and regular, and her temperature was 101.4° F. Soon after her arrival she vomited a large amount of a dark, thick material, in which were large pieces of undigested meat. This material was examined microscopically, but no blood was found. Percussion over the abdomen gave slight dulness on the left side as compared with the right. Patient was calm and talked readily about the accident. The abdominal wound was three and a half inches above the umbilicus, and one-half inch to the left of the median line. The surface of the abdomen was thoroughly cleaned, wound dressed antiseptically, and a small ice-bag applied. Patient was placed in bed and given a hypodermatic of morphiæ sulph. gr. ⅙. It was decided, owing to the absence of urgent symptoms, to delay any operative measures until the next morning.

Morning of November 21. Temperature 102° F. General condition of patient about the same as last night. Slight tympanites present, but no marked increase of pain.

Operation, by Dr. Briddon, November 21st, at 11.45 A.M. The abdomen and thighs were made antiseptic previous to the administration of ether. When the patient was under its influence the abdominal wall was again washed with a solution of hydrarg. bichlor., and afterward by a saturated solution of iodoform in ether. The sponges were kept in warm solution of hydrarg. bichlor., 1 : 5000. An incision was made from the ensiform cartilage to the umbilicus through at least three inches of fat. When the muscular layer and posterior sheath of the rectus were divided, another thick layer of fat was laid bare, on division of which the peritoneum was exposed, nicked, and divided the whole length of the wound. On pressing the stomach downward some bloody serum was found, and in the deeper veins a fluid, which, it was thought, had a milky appearance. The cavity was so deep that an attempt was made to obtain a better view by drawing out the omentum and transverse colon and laying them, enveloped in warm flat sponges, on the lower thoracic wall. This failing to give sufficient room, the opening in the abdominal wall was enlarged downward to a point midway between the umbilicus and the pubis.

The omentum and colon were now returned to the abdominal cavity, and maintained there by flat sponges; the stomach was again examined, and there was found a small rent in the omentum close to its attachment to the greater curvature. This was enlarged by the fingers sufficiently to admit a thorough inspection of the space behind the stomach, where there were found a few coagula of blood. After a prolonged search and examination at that portion of the greater curvature from which the omentum was detached, there were found two linear slits with ragged edges communicating with the interior of the stomach, one of these being situated anterior, the other posterior to the insertion of the omentum, and not half an inch apart.

At this time the condition of the patient was critical, and the indications were to conclude the operation as quickly as possible. Hypodermatics of camphorated ether were used. The perforations were closed by two lines of Lembert's suture. As there was a little adherent omentum at either end of the second row of sutures, a deeper suture was carried through at that point so as to include this, the toilet of those parts above the transverse colon carefully made, and some grumous blood, and what was supposed to be stomach contents, removed. At the suggestion of Dr. Lange, tamponades of iodoform gauze were introduced, one into the space behind the anterior layer of the omentum, the other into the space outside of it.

The abdominal walls were brought together by a number of silver-wire relaxation sutures and intermediate ones of catgut. The superficial dressing consisted of iodoform and bichloride gauze. The operation lasted two hours. The patient's condition was not very promising, and she was immediately placed in bed and surrounded by hot bottles.

Patient recovered from her ether without vomiting. 8 A.M.: temp. 103.2° F.; pulse rapid but regular. Hypodermatic stimulations of camphorated ether given every two hours until the pulse became better. Rectal stimulations of brandy and water given every four hours. 12 midnight: temp. 102° F.; pulse 140; resp. 36.

Nov. 22. Morphia hypodermatically given frequently enough to prevent restlessness. Temperature ranging between 101° F. and 103° F. 4.30 A.M.: temp. 101° F.; pulse 142; resp. 37. 8.30 A.M.: temp. 104.2° F.; pulse 145; resp. 34. Stimulation continued. Urine contained albumen fifty per cent. and large granular casts. 12 M. temp. 105° F.; pulse 145; resp. 24. 12.30 P.M.: a portion of the iodoform gauze removed from abdominal opening. 3.45 P.M.: more gauze removed and two rubber tubes passed to bottom of wound. Ice coil bag used on head and abdomen. 5.30 P.M.: temp. 106° F.; pulse 142; resp. 28. 8.30 P.M.: temp. 106° F.; pulse 150; resp. 17; patient was very restless and delirious. 9 P.M.: temp. 105.4° F.; pulse 150; resp. 15. Pulmonary œdema has begun. 10 A.M.: pulmonary œdema has increased rapidly during past hour; patient is moribund; the œdema is very marked. 11.45 P.M.: patient died.

Autopsy.—Abdomen prominent, both from the thickness of its walls and from distention of the intestines. The abdominal cavity was opened through the original operative incision. Signs of acute general peritonitis at once presented. The intestines were adherent, by recent fibrinous exudations, to the walls of the abdomen and to one another; and the great omentum was attached to the greater curvature and anterior wall of the stomach. In the pelvic cavity there were about ℥viij of a red watery liquid; while in the upper portion of the abdominal cavity there was quite a large collection of a watery, greenish-brown liquid, thought to be fecal. The adhesions were easily separated and the original wound of the stomach with its catgut sutures found. A small portion of the great omentum was found quite firmly attached to the lower part of the closed incision.

The stomach wound was in the greater curvature about two inches from the pylorus. The stomach wound was entirely closed, resisting the pressure of water poured into the stomach. Following the small intestine past the duodenum, four wounds were found in the upper portion of the jejunum, all within three inches. The course of the bullet could be easily traced by several spots of ecchymosis in the tissues. Its direction was downward, backward, and outward. It was found anterior to the left kidney, in the left axillary line, and about one inch below the line of the umbilicus. It was a short No. 32.

The heart was dilated, with flabby walls. The kidneys were slightly enlarged, and showed acute parenchymatous nephritis on gross inspection.

During the time that the stomach wound was being sewn up, the indications for a speedy operation were urgent; and it was probably due to this cause that the wound of the intestine was not recognized.

DR. SANDS asked whether, in laparotomy for gunshot wounds, unless the ball is found or the viscera inspected, there is any means of knowing the distance the ball has traversed, or of knowing the number of perforations.

DR. BRIDDON said that in future he should regard none of his operations as complete until the whole of the intestinal tract had been examined from one end to the other. The duration of the operation was two

hours. There were at least between three and four inches of fat outside the abdominal muscles, and a layer of one inch and a half in the fascia behind the upper end of the sheath of the rectus. It would have been utterly impossible to make anything like a satisfactory examination without prolonging the section downward toward the pubes.

The President remarked that he had never had any opportunity of testing it, but thought the introduction of some bland, colored fluid internally into the wound might develop the existence of apertures in the neighboring portion of the intestine, which could not be conveniently handled; as, for instance, the duodenum; but that even, he thought, might not be a positive test, but yet it might assist in the examination.

Dr. Briddon remarked that there was one peculiar condition in these wounds of the stomach; and that is that they are perfectly linear; when he first saw them he did not suppose they were wounds at all, they looked like linear extravasations of blood. The wounds of the intestines, as a rule, are round or ragged, and sometimes are circumscribed, which are frequently more destructive to the gut or the tissues of surrounding parts; in fact, the wounds of the stomach had been overlooked, and not regarded as wounds; and it was not until the edges were separated that they were discovered.

The President asked if he thought that was not owing to the interval between the receipt of the wound and the operative procedures; he thought that union could take place in that time, as he had seen firm union in six hours.

Dr. Sands replied, but not of the intestines, he thought; in the case spoken of, the intestines were not matted to the stomach or omentum.

Osteoma and osteosarcoma of both superior

Dr. Stimson presented a bony tumor involving both superior maxillæ, which had been removed that day from the girl who had been presented at the previous meeting. The tumor was almost solid bone. At its back was a small, soft outgrowth, like a cap, covering an area of about two square inches. The removal was done rapidly, without much hemorrhage, but the shock was great. The child had rallied under active stimulation and was alive when he left the hospital, but her condition was precarious. He would report at another meeting the details of the operation and the result.

CORRESPONDENCE.

[illegible]

Sir: I have just noticed that Professor F. J. Shepherd, of Montreal, in the January number of *The American Journal of the Medical Sciences*, states in his interesting article, entitled "A Short Account of the Disease called Ainhum," that only two cases previous to his have been reported in North America. The disease is certainly a rare one, although many more cases would have been reported if it was recognized by or familiar to the general practitioner. I reported a case of "Ainhum" in this journal for June 13, 1885, in an article on "Unna's Dermatological Preparations." This case was only reported as *one* in the table of statistics of the American Dermatological Association for 1885, although it might have very properly been reported as *two*, since the negro man, more than a year before he came to the Polyclinic in Baltimore, had lost a little toe from the same disease.

Within a few weeks of the time when this case showed itself, as so often happens, another negro man, suffering with exactly the same trouble in the little toe of his left foot, presented himself. This was the second case reported at the 1885 meeting of our Dermatological Association. Neither of these cases was properly diagnosticated by other physicians who saw them. It is on this account, perhaps, that this disease is so rare. It is also a fact, as Professor Shepherd says, that some dermatologists doubt there being any such distinct disease. To this number I do not belong. The writings and reported cases of others, with those which have come under my notice, have sufficiently proved to me that the disease [illegible]

Very respectfully,
Robert B. Morison, M.D.

AGARIC IN THE SWEATING OF PHTHISIS.

To the Editor of The Medical News,

Sir: Dr. N. S. Lincoln called my attention to the powerful influence of pulverized agaric to control the sweating of pulmonary phthisis; since then I have used it in five cases, with the greatest success.

In the first case I prescribed the powder in ten grain doses at bedtime. Owing to its cathartic effect I reduced the dose to five grains. Continuing this for a week, all sweating ceased. I now, in this case, only use it when a slight moisture of the skin during the night warns the patient that he may be going to have a return of the sweat. In one case I had to repeat a five grain dose every two hours, three times one night; no cathartic effect resulted. I call your attention to this remedy because, when I first ordered it I found great difficulty in obtaining the smallest quantity, either of the powder, the alkaloid, or the fluid extract. The remedy, while so effectual in controlling the sweating, did not help the cough or produce drowsiness.

Armistead Peter, M.D.

BERI-BERI.

To the Editor of The Medical News,

Sir: The paper of Dr. Seguin on Beri-beri in your issue of December 18th, calls to my mind an outbreak of disease which occurred several years ago on a Provincetown bass fishing vessel, and which I, having seen two of the cases, reported in the *Boston Medical and Surgical Journal*, 1881, ii. p. 400, under the head of "A Curious Endemic." I was entirely at a loss at the time as to the real nature of the disease. Dr. Costello, of Vevay, Indiana, expressed the opinion that the cases were Beri-beri (*op. cit.* p. 577), an opinion which I then could not share, but which I now believe to have been correct. Out of the crew of nineteen men fifteen were one after another attacked by pain and numbness

of the hips, which was soon followed by œdema involving not only the legs but also the trunk to a greater or less extent. One man died; the rest recovered sooner or later. Careful investigation failed to reveal any cause to which the outbreak could be assigned. I repeat that I am now satisfied that the disease was Beriberi. At that time this disease had never been reported as occurring in this country except in a number of sailors from a Brazilian man-of-war treated in a hospital in San Francisco, nor was it known at that time that Beriberi is a peripheral neuritis.

Yours very truly,

FREDERICK C. SHATTUCK.

BOSTON, December 22, 1886.

NEWS ITEMS.

SURGEON-GENERAL GUNNELL, in his report to the Secretary of the Navy, invites attention to the condition of the Medical Corps of the Navy. Its vacancies have not been filled for several years, resignations, deaths, and retirements have depleted it more rapidly than candidates have been obtained. The bureau has not been willing to lower the standard of requirements; and it is impossible with the present inducements offered, to find young medical men possessing the necessary qualifications who are disposed to become medical officers of the navy. The Army Medical Department has qualified applicants far in excess of its needs, attracted by better pay, well-defined rank, and more satisfactory professional position. Since 1870 more than thirty young medical officers have resigned (three of them to enter the army corps). He says he cannot too strongly recommend that prompt measures be taken to increase the advantages and improve the condition of this department.

DR. A. C. BERNAYS has been appointed by the St. Louis Board of Health consulting surgeon of the City and Female Hospitals.

A LIST OF PATENT MEDICINES, the importation of which the Russian Government has decided to prohibit, has recently been published. It consists of about 800 preparations of English, American, French, and German origin, the English or American numbering nearly 100. Pills, plasters, hair restorers, cough drops, medicated foods, ointments, and many miscellaneous preparations for a great variety of purposes are all classed together in one long medical *index expurgatorius*. The list appears to have been drawn up by a committee of Russian physicians, and even such remedies as taraxacum and podophyllin have been struck out.

CHINESE TREATMENT OF CHOLERA.—The Chinese have a rather radical cure for cholera. A Shanghai paper says that on July 22 a Chinaman employed on one of the steamers was taken ill, apparently with cholera. The following is the course which was adopted, according to the paper from which we quote: "His friends immediately sent for a native doctor. This individual had with him a box containing some long needles, and these he used on the patient. A needle was driven some distance into the man's head, near each temple, and again behind his ears. In each case bleeding followed. Needles were also driven into the lips, both sides of the chest, both sides of the stomach, and also into the pit of it. The doctor then scraped the skin of the man's throat till it looked like the neck of a turkey. This violent treatment had the desired effect, and in a few hours afterward the man was quite well, and eating his midday meal with evident relish."

DECREASE OF THE ENGLISH DEATH-RATE.—The English Registrar-General shows, from a review of the mortality of England during the ten years (1871–80), that the mean annual death-rate has fallen to 21.27 per thousand, the lowest average since civil registration began. With this general fall is an increase in the death-rates in the later periods of life. This is also significant of improved tenure of life, for it shows that a larger proportion of persons live to be old enough to die in the later periods. Dr. Ogle gives the credit of the lessened death-rate among young people to improved sanitation, which has removed many fruitful sources of mortality, while by aiding the survival of weakly persons it may have had a tendency to increase the death-rate of the later periods. The changes in the death-rates, Dr. Ogle adds, "have given to the community an annual addition of 1,800,047 years of life shared among its members; and, allowing that the changes are the direct consequence of sanitary interference, we must regard this addition of nearly two million years of life as an annual income derived from money invested in sanitation."

LEAD-POISONING THROUGH HOME-MADE WINES.—The fact that an article is "home-made" is usually a sufficient guarantee of its purity and wholesomeness, whatever other qualities it may lack; but an exception to this general rule has just been discovered by Dr. D. Campbell, the medical officer of health to the Calne Local Board. It appears that, for many years past, Dr. Campbell has had occasion, about the months of August, September, and October, to attend many severe cases of acute and subacute lead-poisoning, the source of which he could not ascertain. The drinking-water, the beer, the tea, the coffee, and bread, as well as the various cooking utensils, all fell under suspicion and analysis, but with only negative results. A few weeks ago, however, seven severe cases—two almost fatal—occurred simultaneously in Calne and the neighborhood, and careful inquiries by Dr. Campbell elicited at last from one of the patients the fact "that her husband had drunk some home-made rhubarb-wine, which she herself had made, and which she was sure could not contain any poison of any sort, as she was very careful in selecting and cleaning her rhubarb; and, as for the sugar and barm, they were all right; besides, the vessel was a beautifully clean, glazed, earthenware pan, in which she steeped it for a fortnight or three weeks to ferment." Here Dr. Campbell at once saw the solution of the problem that had so long been puzzling him. The glaze on these earthenware vessels contains as much as 60 per cent. of white or red lead, and, during the process of fermentation, the acids of the rhubarb, or of any other fruits used, with the acetic acid generated, act on the glaze, dissolve the lead, and form acetate, or sugar of lead, which is a powerful irritant poison when taken even in

small doses for any length of time. Analysis of ten samples of various home-made wines collected by Dr. Campbell, showed the presence of lead in large quantity in eight; one (parsnip), which was made in a galvanized iron tub, contained iron; and one, which had been made in an ordinary boiler, was free from lead and iron. One sample, which was five years old, and two samples, which were two years old, contained lead. Various chemical tests, applied to the earthenware vessels that had been used showed whence the lead had been obtained. As high as the liquor had reached in the vessel, the glaze was more or less dissolved off. On acetic acid and iodide of potassium being applied, a clear yellow spot of iodide of lead was produced; and, on ammonium-sulphide being applied to the denuded part of the pan, a distinct black line was immediately formed, clearly showing the presence of lead in the glaze. It is not an uncommon custom in country districts for persons who have large gardens and much fruit to make considerable quantities of these wines, from rhubarb, parsnips, red and black currants, sloes, damsons, elderberries, etc., for use by the men in harvest-time. It is, therefore, important that they should have the timely warning of the danger that lurks in those "beautifully glazed earthenware pans." Doubtless, wooden vessels would be quite as convenient for these domestic brewings, whilst they would be free from the risk of lead-poisoning.

GIFT TO THE PASTEUR HOSPITAL.—The Emperor of Russia has sent a magnificent donation of forty thousand roubles ($20,000) toward the erection of the proposed Pasteur Hospital, in Paris. With this new addition, the hospital fund now amounts to $320,000, a sum sufficient to erect a fine building.

MEDICAL SECTS AND CLINICAL INSTRUCTION IN PUBLIC HOSPITALS.—An interesting article appeared recently on this subject in the *Boston Medical and Surgical Journal*. The homœopathists of that city petitioned the managers of the City Hospital for equal privileges in that institution with the regulars. The trustees considered the request with great fairness, and deliberated long and carefully before making an answer. Circulars were sent out to all institutions where physicians and surgeons of both schools were supposed to be on the attending staff, to learn the practical workings of this arrangement in other places. This dual arrangement was found to exist in only two institutions, so far as answers were received. And in these two instances it was by no means satisfactory. Thereupon the trustees replied to the petitioners that the granting of the request would necessitate radical changes in the management of the hospital.

Three possible plans suggested themselves. Homœopathic practitioners might be added to the attending staff, with a full share in all the latter's rights and privileges. Certain wards in the present buildings might be placed under the control of the petitioners, or new wards might be constructed for them. The trustees were not empowered to make such a radical change in management, as the adoption of these plans would necessitate. The petitioners were, therefore, courteously referred to the proper authorities, namely, the City Council.

In regard to clinical instruction, it was decided that the attending surgeons might operate before the students in the amphitheatre on certain days, and that all physicians and all matriculants of one year's standing, at a legally established medical college, might be admitted. This rule was held to apply to female students. The operator might, if he chose, request the withdrawal of students of either sex in certain cases requiring exposure. No male visiting students were to be allowed to witness any operation on female patients requiring exposure of the genitalia. Students, not exceeding twenty in number, might accompany a member of the staff in his daily rounds.

NOTES AND QUERIES.

[redacted]

SIR: The abdominal tourniquet, which usually passes under the name of Syme's, will be found figured in the London *Medical Record* for April, 1825, and is the invention of Mr. H. Searle, a surgeon in London, over sixty-two years ago. A. H. A.

GASTROTOMY.

[redacted]

SIR: In connection with the report by Prof. Bernays of his successful gastrotomy and his table of similar cases, it may be of interest to your readers to learn that in the diary of John Evelyn there is mentioned a similar successful case. In August, 1640, Evelyn visited Leyden, and while there saw the anatomy school, theatre, and "repository." Of the latter he thus speaks: "Amongst a great variety of other things, I was shew'd the knife newly taken out of a drunken Dutchman's guts by an incision on his side, after it had slipped from his fingers into his stomach. The picture of the chyrurgeon and his patient, both living, were there."

ORIGINAL LECTURES.

INTERSTITIAL NEPHRITIS, WITH HYPERTROPHY OF THE HEART AND HEMORRHAGE INTO THE BRAIN AND NASAL MUCOUS MEMBRANE.

Abstract of a Clinical Lecture delivered at the Montreal General Hospital.[1]

BY R. L. MACDONNELL, M.D.,

PROFESSOR OF HYGIENE IN McGILL UNIVERSITY AND PHYSICIAN TO THE MONTREAL GENERAL HOSPITAL

GENTLEMEN: It is my purpose this morning to occupy your attention with the consideration of the clinical history of a case which you all have had an opportunity of watching for the last six months or more, the physical signs of which you have had repeated opportunities of examining for yourselves, and you have noted from day to day the steady progress of the morbid processes. The patient I allude to is Eliza H., now in No. 24 ward, a small, spare woman of about forty years of age, who entered the General Hospital on the 9th of September, 1885, complaining then of certain definite symptoms—symptoms which ought to have led and did lead us directly to the diagnosis of the disease. These were increasing debility, a slight cough, frequent and severe attacks of epistaxis, sickness, and vomiting, usually at its worst in the early morning. And in addition to these, for two months previously her feet had been swollen.

Now let us consider the meaning of these complaints of hers. Her age is that for visceral disease; diseases of the kidney and liver and malignant disease belong to this period of life. The physical examination of the lungs will tell us the meaning of the cough, but the combination of morning vomiting, bleeding of the nose, and dropsy of the feet is very significant, and points to renal disease, more especially that form known as the contracted kidney. Non-traumatic epistaxis is always a symptom deserving of close investigation; occurring, as in our case, in a person of forty, it always means mischief. The venous system is overloaded, or the arteries are brittle, or the heart is enlarged and too strong for the arteries, hence we meet with it as a symptom in portal obstruction when the venous channels are all too full, and in heart diseases, more especially when the left ventricle is hypertrophied, and, lastly, in Bright's disease, where two causes work together. Not only is the heart-muscle too strong but the bloodvessels are too weak, and so breakages are apt to occur in weak places; one of these is the nose, the other the brain, as we shall presently have an opportunity of seeing.

Sickness at the stomach and morning vomiting occurring in a person of forty, should excite suspicion. There are three common causes. Pregnancy is one, but that, it has been ascertained, is not her condition. Alcoholism is a common and often an overlooked cause of this kind of dyspepsia, especially in the form of dram drinking. We are assured of her temperate habits. Visceral disease is the third main cause, and this leaves us to investigate the question as to which organ is the seat of disease. In the very early stages of contracted kidney as well as in an early stage of interstitial hepatitis, we meet with morning nausea and vomiting. It will rest with the remainder of our examination to decide as to which of these conditions is present.

Œdema of the feet points most commonly to cardiac complications. Remember the broad rule that dropsy of the feet alone means heart, dropsy of the belly alone means liver, and dropsy of all the body means kidneys.

The illness altogether dates back two years, ever since she came to this country. Previously she had always been in very good health. For the last seven years has been widowed. Had several children, with hard labors, and four miscarriages.

The very first symptom which made its appearance, was dyspnœa upon exertion, which was soon followed by dropsy of the feet, a slight cough; night sweats, and loss of flesh; occasional epistaxis, and the morning vomiting. For the relief of these she entered the Montreal General Hospital two years ago. It was found noted in the case book, that, although there was evidence of cardiac hypertrophy, there was none to show that the kidneys were implicated. In the summer of 1885 she was again a patient here, and came for the first time under my care. She was then slightly anæmic, the muscles flabby and soft, the tongue moderately coated, the bowels constipated. The pulse beat at ninety to the minute, but its character was noteworthy. It was unusually full and strong, hard and incompressible; in fact, it was the "pulsus durus et tardus et magnus," the renal pulse. Such a pulse would make one suppose that there existed a hypertrophied heart, and such, indeed, was the case; for the impulse was strong and heaving, and pulsation was visible in all the superficial arteries. The apex beat could be felt just inside the left nipple line in the left intercostal space, and the area of superficial cardiac dulness was correspondingly increased.

On auscultation, no murmur was heard, though at times it was observed that the first sound was accentuated. Both sounds were unusually loud. Physical examination of the lungs and abdomen yielded negative results.

We were now able to exclude liver and lung disease from our diagnosis. A hypertrophied heart existed, probably without valvular disease, a condition not very often met with apart from disease of the kidneys. To determine this the urine must be examined. The total quantity passed per diem was in excess of the normal. The fluid itself was of normal color, with a heavy mucous cloud. Sp. gr. 1.020; acid reaction; no sugar. On adding nitric acid, and boiling, the urine becomes slightly

[1] Delivered in the regular course of Clinical Lectures in the Summer Session of 1886.

cloudy, and when allowed to cool and settle, this cloudiness sinks and resolves itself into a very distinct sediment. Hyaline casts in small numbers were found on microscopical examination, together with a considerable quantity of renal epithelium and oxalates.

From this examination the important fact of the presence of albumen is learnt. What, in this case, is the likely cause? It depends upon disease of the kidney, because there is evidence of kidney degeneration in the presence of hyaline casts. Otherwise it might be argued that the condition of the heart caused the albuminuria, as is indeed often the case. Moreover, the symptoms not only point to renal disease generally but to one particular form, that known as interstitial nephritis or the granular kidney. The distinctive points in the history, as given so far, being 1. The initial symptoms, the dyspnœa the first symptom as it often is, the gastric disturbances, the epistaxis, the œdema of the feet. 2. The condition of the circulatory organs, hypertrophy without valvular disease, and generally increased arterial tension. 3. The urine is characteristic and makes the diagnosis almost certain. The large quantity, the low specific gravity, not so low as commonly noted in such cases, but still low, and the small amount of albumen. In the other form of chronic nephritis known as the large white kidney, which closely resembles the disease of which we are speaking, the amount of urine is smaller and the albumen is in it in large proportion. And, lastly, casts of the hyaline variety were found. The presence of hyaline casts with albuminuria may be taken as a sure indication of structural renal disease.

The ophthalmoscopic changes so frequently met with did not occur in our patient.

During the summer of 1885 the progress of the disease was stationary, but in the early autumn severe stomatitis set in, accompanied by such depression of the general strength that a fatal result from exhaustion at one time seemed imminent. There was extensive ulceration of the mucous membrane of the mouth, the gums receded from the teeth leaving the teeth loose, so that some of them had to be removed. A large ulcer threatened to destroy the floor of the mouth and gave rise to several severe hemorrhages. This is an uncommon affection, and, so far as my knowledge goes, has no connection with the renal disease.

Mrs. H, having recovered from the stomatitis, left the hospital and went into service.

So far, then, we have the history of a case of granular kidneys with hypertrophied heart and rigid vessels. What are the probabilities of such a case? A too strong heart with too brittle arteries: a break is likely to occur somewhere. She did well until last February (1886), when she found her left hand very weak, and a few days after noticing this she awoke one morning to find her whole body numb. Shortly afterward cramps set in in both limbs, but after a time the left side became entirely helpless. She remembers nothing further until she found herself back again in the hospital for the third time. What was the nature of this seizure? Was it embolic, hemorrhagic, or uræmic?

It is likely to have been embolic, on account of the heart lesion, a strong suspicion having always existed of the presence of valve disease, but hemorrhage was much more probable. In chronic Bright's disease, especially that form of it which in this case we believe to exist, there is a chronic affection of the vessels, the result of which is that they become brittle and unyielding, a little extra force, and they break, and hemorrhage occurs. This change in the vessels, of the nature of which your instructor in pathology will inform you, is accompanied by high arterial tension, giving rise to a pulse the characters of which have been already described. Now both these conditions are accompanied by a hypertrophied heart, so that I am correct in saying that hemorrhage is a likely event, and such is the result of observation in such cases. The vessels give way where least supported, that is most commonly in the soft structure of the brain itself, or in the mucous membrane of the nose. You must remember that in the latter situation hemorrhage has already occurred.

As to the uræmia having been the cause of the seizure, I think it unlikely. There were no convulsions observed, which is the form of attack commonly adopted, and there was distinct and persistent hemiplegia, a remarkably rare occurrence in uræmia, so rare that you need not take it into consideration.

We must, therefore, add to our diagnosis hemorrhage into the right side of the brain. On the 18th of February, the day of her third admission, the patient was in a condition of semi-coma with left hemiplegia. The mouth was drawn to the right side; the tongue deviated to the left; pupils sluggish; left arm powerless, and devoid of sensation; left leg paretic. Plantar and patellar reflex both present. Sonorous râles were heard in both interscapular legions, but in other respects there were no changes in the physical signs. The amount of albumen in the urine had greatly increased, and the hyaline casts had become more numerous.

In this condition our patient remained for two months, the hemiplegia gradually disappearing until she could raise the left arm to the chin, when a condition of chronic uræmic poisoning set in, and in that state she now lies.

When we made our visit a week ago we found the patient in a very serious condition. She complained of severe headache and oppressive drowsiness, the two symptoms by which, in most cases, fatal uræmia is ushered in. On closer examination it was found that she had had slight tremors in the affected arm and leg, which lasted but a few moments. Since that time she has remained in a condition of chronic uræmia, the sleepiness and the headache remain, and it was noted that the latter was especially painful in the front of the head, a characteristic of uræmic headache. At times, additional hemorrhages occur from the nose, and there have been lately several profuse ones. The specific gravity of the urine has become lower, being now 1.010, and albumen is present in much larger proportions. Her condition is now critical, another cerebral hemorrhage and a fatal result may ensue, or, what is more likely, the uræmia may deepen, and death in a comatose condition occur.

Postscript.—The death of the patient in a comatose condition occurred some two weeks after the delivery of this lecture. Both kidneys were contracted, the heart hypertrophied. There were a few spots of atheroma in the aorta, and the mitral valves were decidedly roughened. In the right hemisphere of the brain the remains of a large blood clot were found, showing the cause of the hemiplegia.

ORIGINAL ARTICLES.

FURTHER OBSERVATIONS ON THE BLOOD IN CASES OF MALARIAL FEVER.[1]

By W. T. COUNCILMAN, M.D.,
Associate in Pathology, Johns Hopkins University

In view of the frequent publications which have of late been made in this field, it will not be necessary to give more than a cursory review of the literature. Omitting the publications of Klebs and Tommasi Crudeli on the bacillus malariæ, the first publication in which an organism is described differing from this and apparently belonging to an altogether different group of organisms, was made by Lavaran in 1881. He described in the blood of malarial patients an organism which he named the oscillaria malariæ. It appears under four forms, which, though differing from one another in size and shape, he regards as different stages of development of the same organism. He describes them as bodies No. 1, 2, 3, and 4, respectively.

Body No. 1. Usually of a crescentic shape, slightly longer than a red blood-corpuscle, with pigment granules in the centre which are generally arranged in circular form.

Body No. 2. Small circular bodies smaller than a red corpuscle to which they are usually attached, sometimes occurring singly, at others in groups of two or four. They contain pigment granules arranged in a circle.

Body No. 3. Somewhat smaller than a red corpuscle, of round or slightly irregular outline, pigmented in the centre, and provided with three or four long cilia by means of which they move rapidly in the blood. In addition to these ciliated organisms there are free cilia which move rapidly through the blood.

Body No. 4. Similar to body No. 3, but has no cilia, and apparently represents the cadaveric form of body No. 3.

Lavaran supposes the free cilia in the blood to be the adult form of the organism, the other forms representing stages in its development. In the scheme that he forms the cilia develop in bodies No. 1 and 2, finally pierce the enveloping membrane, remaining attached by one end (body No. 3), and after a time sever their connection with this and become free. The hull remaining after the escape of the cilia is body No. 4.

Next to Lavaran's, the most important publication is that of Marchiafava and Celli made two years later. These authors describe as constant in the blood of malarial patients an amœboid organism, whose habitat is inside the red blood-corpuscles. Its most striking feature is the amœboid movements. It changes both its shape and relative position inside the corpuscle, and is always found during the paroxysm of intermittent fever in patients who have not taken quinine. Its size varies in wide limits, sometimes pigment granules are found irregularly distributed through it, especially if the blood examination is made at the termination of the paroxysm. In addition to this body they saw the crescents discovered by Lavaran and ciliated organisms, the latter but four times in the first forty-eight cases examined and not once in one hundred and twenty cases examined afterward. They regard the amœboid organism, the credit for the discovery and exact description of which certainly belongs to them, as the pathogenic organism in the disease, and have named it the plasmodium malariæ.

In an article which appeared in the *Medical Record*, for May, 1886, Dr. Sternberg reports a case in which he discovered the plasmodium in blood taken from a patient in the beginning of a paroxysm of intermittent fever. In a paper read before the Association of Physicians and Pathologists in June, 1886, I have reported sixteen cases of acute intermittent fever, in all of which blood taken during the paroxysm contained the plasmodium. All these observations were made on acute cases and *only* the plasmodium was found.

During the present autumn good opportunity was given me for a further study of the blood, there being an unusual number of cases of malaria at Bay View Asylum, which were kindly turned over to me by Drs. Atkinson and Rohé, the physicians in charge. In all, 80 cases were examined, some of these on ten or more separate occasions and others but once. The 80 cases embraced all the forms of malarial disease common to this section. I have divided them into cases of intermittent fever, remittent fever, malarial cachexia, and comatose malarial fever, the *fievre comateuse pernicieuse* of French authors. The blood in most cases was examined fresh, although numerous examinations were made after drying on the cover slip, and subsequently staining with some of the aniline colors.

The cases of intermittent were nearly all of the tertian form, only a few, 4 in all, were quotidian. There is considerable difference in the blood in intermittent fever depending on the length of time from the beginning of the attack. In the first days of the attack plasmodia are found only during the chill. They are small, and extremely difficult to see, the difficulty being increased by irregularities on the surface of the red corpuscles and a vacuolation, or what appears to be this, inside of them. They may or may not be pigmented, the pigmented forms being seldom found in the first few paroxysms, but later most of them are pigmented. The plasmodia appears as pale homogeneous masses inside the red corpuscles. They are either round or irregular in shape, the irregularities taking the form of round knob-like projections. Their size varies from one-third to one-fourth the diameter of the corpuscle up to a size almost or wholly filling the corpuscle, which in this case is larger than ordinary and almost completely deprived of pigment. Sometimes the corpuscle apparently contains two or more of these bodies, but on staining it is seen that the apparently isolated masses are connected by extremely slender protoplasmic filaments.

The index of refraction of these bodies is almost the same as that of the blood corpuscle which contains them, and they are most easily seen when round. The most remarkable thing about them is their

[1] Read before the Clinical Society of Baltimore, November, 1886.

amœboid motion. This is readily seen, and takes place with about the same rapidity as the movements of the ordinary fresh water amœba. While watching them I have seen them disappear, and then slowly reappear in the corpuscle. This is easily explained by their spreading out in a thin layer, their refraction then being so low that they cannot be distinguished from the surrounding corpuscle. As they contract and become thicker they again become visible. In such cases the appearance of amœboid movements will settle the question. Some care is necessary in collecting the blood. The coverslip should be clean, a very small amount of blood be placed on it, and applied immediately to the slide. When the amount of blood taken is so large that the corpuscles lie over each other, or when they are in rouleaux, it will be impossible to see the bodies. They are much more readily seen in stained preparations. These are made by drying a thin film of blood on the cover slip, taking care to have not more than a single layer of corpuscles, heating the cover, and staining with some one of the aniline colors, for which purpose fuchsin or methylene-blue will give the best results. At this early stage of the disease, the bodies are not found in the period of apyrexia, and appear to be most numerous at the height of the algid stage.

After the patient has had several chills, the bodies are found also in the interval, but in greatly less numbers than in the paroxysm. They are much more easily seen, and present numerous differences from those just described. The small non-pigmented forms are found, but, in addition, larger ones, which almost or entirely fill up the body of the red corpuscle. These larger forms are always pigmented, the pigment generally taking the form of minute black rods. It may be irregularly distributed through the body, or collected in a mass at one side. The corpuscles containing these large bodies are generally slightly swollen and very pale, at times apparently entirely wanting in color. The pigment renders the detection of these bodies a matter of comparative ease. In using the Abbe illuminator, the diaphragm may be thrown out entirely, and only the pigment sought for, and, when this is found, the character of the body containing it may be ascertained by replacing the diaphragm (Fig. 1). The pigment granules often exhibit the

at without the diaphragm. The upper line with the diaphragm in place. $\frac{1}{12}$ homogeneous immersion.

most marked Brownian movement. The amœboid movement can be readily followed even without the use of the diaphragm, by observing the relative position of the pigment masses. In addition to these bodies, several times bodies resembling the larger forms of the body No. 2, of Lavaran, were found.

Only two cases of well-marked remittent fever came under observation. In both of these, and in all the cases of malarial cachexia, bodies were found which differed from those just described. In preparations of the blood, taken at any time, long bodies usually curved in the form of a crescent, were found. These bodies are highly refractive, homogeneous, with sharp outlines, and always contain pigment. This is usually collected in a bunch in the middle of the body. In a few of the bodies the mass of pigment was in the centre, and from this long lines radiated toward the extremities. Most of the forms are slightly curved in the form of a crescent; they are from one and a half to three times as long as the diameter of a red corpuscle, and not wider than the half of this diameter. Though they are narrower at the ends than in the middle, the ends are not pointed but slightly rounded. While this is their general character, they present considerable irregularity, some being nearly round, others elongated and straight. It was in the oval ones that the radiating arrangement of the pigment was most frequently found. They are free in the blood and have no power of motion; they are most generally found in the midst of clumps of red corpuscles. In several cases a faint, delicate line, curved the other way, was seen connecting the ends of the crescents. Marchiafava and Celli also describe these crescentic forms, and suppose them to be developed from the plasmodia. (Fig. 2.)

Various forms of c[illegible].

In two cases the crescents were found in the blood at the same time that the red corpuscles contained plasmodia. These were two cases which had come into the hospital with intermittent fever, which ceased under the influence of good food and a placebo mixture composed principally of tincture of gentian. There were abundant plasmodia in the blood during the entire period that the chills lasted; they became fewer with the appearance of the crescents, and three days after the last chill they had disappeared entirely, but the crescents remained as long as the patient was under observation.

All the cases of malarial cachexia were persons who had lived in a malarial country, coming principally from the packing-houses of Hartford County, and from the large peach farms in the lower counties. Most of them had suffered from repeated attacks of intermittent fever, and presented all the appearances of malarial cachexia, anæmia, enlarged spleen, slight icterus, etc. Although most of these

cases were kept from quinine while under observation, none of them developed acute forms of malarial fever. The number of crescents varied much in the different cases. In one case of remittent fever with comparatively high temperature, splenic tumor, and slight icterus, they were so numerous that, often twelve to twenty could be counted in a single field of the homogeneous immersion. In the other case of remittent fever they were not so numerous. In the cases of malarial cachexia they were not so numerous as in the cases of remittent fever. It could not be said that the number of them bore any exact relation to the severity of symptoms. One of these cases in which they were well marked left the hospital in a state of comparative vigor after a long course of iron and tonics, and on my last examination, made the day he left, they were found in considerable numbers. In one case, with large spleen, marked anæmia, general malnutrition with œdema of lower extremities, they were present in extremely small numbers. Their numbers did not vary much from day to day. These bodies seem to be peculiar to forms of malaria other than intermittent fever. In not one case of tertian or quotidian fever were they found. They were found in cases where the chills had stopped under slight tonic treatment and better diet. In most cases where they were found, they continued during the entire stay of the patient in the hospital. In one case they seemed progressively to become fewer in number, and when the patient left the hospital but a single one could be found in the examination.

Four cases of the pernicious comatose form of malarial fever were investigated. This is a form of fever which is rather rare in and around Baltimore, and still more rarely recognized. Seven cases of it have come to the autopsy table at Bay View in the last two and a half years. Five of these were brought to the institution in a state of coma, two developed in the house. All of the cases had about the same symptoms: a sudden attack, coma which became gradually deeper, and fever rarely going above 102°. In most of these cases there was albuminuria.

Of the four cases seen this fall, three were fatal. In one case the blood was examined on the admission of the patient, and the diagnosis made. He was given at once sixty minims of the solution of quinine and urea, and after a few hours fifty minims of the same solution. On the following morning his condition had much improved, and after large doses of quinine for ten days, he was able to leave the hospital. In one of the fatal cases the blood was examined before death, and the diagnosis made, but in spite of the vigorous use of quinine hypodermatically he died. The patient, however, had been comatose for forty hours before the examination of the blood was made. In another case the examination was made directly after death and the condition diagnosticated.

In all of these cases the crescentic bodies were found in great numbers, along with other bodies which were seemingly identical with the hyaline bodies found in the capillaries after death. In the case which recovered there was some diminution in the number of crescents from day to day, but the small round pigmented bodies disappeared entirely. The characteristic lesions were found after death. The cortex of the brain was a dark chocolate color, the liver and spleen much enlarged and deeply pigmented. Microscopically the characteristic hyaline bodies were found in immense numbers in the internal organs, particularly in the brain and spleen.[1]

Often an appearance similar to segmentation was seen. Instead of the single hyaline body with the pigmented centre, it seemed to be split up into a number of much smaller bodies, four to eight small stained bodies were found together, all apparently enclosed in a capsule. One case differed from the others in the small amount of pigment which was found in the hyaline bodies. In all the cases a few non-pigmented forms could be found, but in this they were nearly all unpigmented. When very thin sections of the spleen, made by embedding portions of the organ, were examined, the numbers of these bodies found almost exceeded belief. The tissue was literally packed with them, and in numbers they could only be compared with the bacilli found in the same organ in cases of anthrax. Although numerous crescents were found in the blood examined during life, none were found in the organs after death. In the blood examined during the autopsy only the hyaline bodies and some imperfect forms of crescents were found.

Though the bodies here described leave little doubt in the mind of the observer that they are foreign to the organism, and could not have arisen in consequence of any transformation of protoplasm, there can be no doubt as to the character of the ciliated bodies. These with the crescents were the most frequent forms seen by Lavaran. They were also seen by Marchiafava and Celli in four of the cases examined by them. These ciliated bodies are from one-third up to one-half the diameter of a red blood-corpuscle. They always contain pigment, have sharp outlines, and about the same refraction as the crescentic organisms. The pigment is either arranged in a circle or distributed through the mass. In the latter case it shows the most active Brownian movement. The cilia vary in number; usually there are but two, but in some cases as many as four were found. They appeared always to be arranged on one side of the body. Their length is three or four times that of the body to which they were attached. They are thin, delicate filaments with slight nodular swellings at intervals, and they most always terminated in a small node. They are best seen when moving slowly. When their motion is rapid only a glimpse can be caught of one now and then, as it comes across the focus of the microscope; and when they are not in motion they can be seen only with the greatest care in focussing.

Several times in the same preparation with the ciliated bodies free cilia were seen. These appeared to be the same size as those attached to the bodies, and like these had small nodes along them. They moved rapidly through the blood, sometimes with a spiral motion, at others with a lashing motion similar to that of a spermatozoon. (Fig. 3.) In their on-

[1] American Journal of the Medical Sciences, April, 1886.

ward motion they often came in contact with a red blood-corpuscle and would violently indent this, or they would agitate a whole group of corpuscles. The motion of the cilia, both when attached and

Ciliated bodies and free cilia. $\frac{1}{50}$ homogeneous immersion.

when free seemed to have a certain rhythm: they would move slowly at first, the motion increasing until it became very rapid; then it would become slower and nearly cease, again to become very rapid. In addition to the motion of the filaments, a wave-like motion of the periphery of the body was often seen.

The description of the ciliated bodies given by Lavaran agrees with what I have observed, but he figures them as somewhat larger than they actually are. They were found in eleven of the seventy-six cases, and in every form of the disease. In one of the cases of comatose fever examined before death they were seen, but not in any of the examinations made after death. In addition to this case they were found in one case of remittent fever, in five cases of typical intermittent, and in four cases of malarial cachexia along with the crescents. Their presence was not constant. Sometimes they were seen but once in a case in the course of ten or twelve observations, in other cases they were seen three or four times. Several times small hyaline masses about as large as one of the larger forms of micrococci were found attached to them.

Most of the cases were seen during a residence of two weeks in the institution, and some rather interesting results as to the action of drugs on these bodies were obtained. In order to study the cases as thoroughly as possible, most of those coming in with simple intermittent fever were placed under placebo treatment, good diet, and rest. Under this the chills in some cases diminished in frequency and severity, and in a few instances ceased entirely. Others grew worse, the chills antedating and gradually changing from a tertian to a quotidian type. In several cases the plasmodia disappeared from the blood and crescents appeared. In all the cases of intermittent fever a few large doses of quinine sufficed to stop the chills and cause the plasmodia to disappear from the corpuscles. The quinine was given in doses of ten grains t. d. for several days in succession, after which the patients were given smaller doses or placed on house tonic. Similar treatment in cases in which the crescents were present seemed to have absolutely no effect on them. They would be present in just as great numbers after thirty grains of quinine had been given daily for three days as before any quinine at all was given. Knowing the effect of Warburg's tincture on cases of chronic malaria, this was given in two cases in one-half ounce doses t. d. for several days in succession, but with no more effect on the bodies than the quinine had had. The patients improved, appetite and color became better, but the bodies remained, although, as said, their number in some cases was diminished.

I am able to say little as to the effect of medication on the ciliated bodies. In some cases they were not seen after quinine, but often they were seen but once in the course of many examinations, so that little can be learned from this. In one case they appeared after numerous doses of quinine had been administered. In one case Dr. Atkinson was kind enough to draw some blood from the spleen in an interval of the attack, in a case of intermittent. In the splenic blood the plasmodia were found in considerable numbers, but they were not present in the blood drawn from the finger on the same day. In every examination special attention was directed to pigmentation of the white corpuscles. Pigmented white corpuscles were found in comparatively few of the cases, and only in the severer forms. They were most numerous in the case of a negro, with comatose fever, and were found in abundance in the three other cases. In these the pigment was in the shape of large, round and irregular masses. It was not found in any of the recent cases of intermittent fever, and only occasionally in cases of remittent fever and malarial cachexia. In these cases it was mostly in the form of fine rods.

Changes were seen in the red corpuscles in numerous instances. The most common change was the appearance of vacuolation spoken of. This is important as liable to lead to error, and seems most probably what Richard has described as the first appearance of the parasite in the corpuscle. This he describes as a small, clear spot appearing in the corpuscle, somewhat as a weevil appears in a pea. In the cases where the anæmia was marked there was a diminution in the number of red corpuscles, and considerable variation in size and shape.

Some attention was directed to the blood plates. In our observations last spring it appeared in some cases that these were pigmented, but I was unable to confirm this in the cases examined this fall. Sometimes their numbers appeared to be increased, but this varied so much in specimens of healthy blood examined, that I could not reach any definite conclusion. The white corpuscles containing the pigment, and others which did not contain it, were in many cases enormously swollen. None of the white corpuscles contained the plasmodia, but in one or two instances the movable bodies seemed to be enclosed in them.

Numerous control experiments were made, the most convincing of which were unintentional. Cases of marked anæmia from various causes other than malaria were examined, cases of typhoid fever, and of fever from various causes: but all with negative results. In several instances individuals from a malarial region with almost every outward manifestation of malaria, slight jaundice, etc., were examined, supposing as a matter of course that they were malarial, and negative results obtained. One of these individuals not only had the outward ap-

pearance, but so typical a remittent fever temperature curve that it required considerable resolution to stand by the microscopic diagnosis. The further course of the disease justified the confidence.

As the matter stands now so much is certain (1st) that in malarial fevers and cachexia there are certain bodies found in the blood, whose presence makes the diagnosis of the disease certain. 2d. The character of these bodies varies in different forms of the disease. Although they seem in rare cases to run into each other, still, in general, we can say that where the plasmodia inside the red blood-corpuscles are seen the patient has intermittent fever, and where the crescentic and elongated masses are found he has either some form of remittent fever or malarial cachexia. The ciliated bodies, though diagnostic of the disease, do not afford any indication of the character of the fever. What is the nature of these bodies? That they are organisms, whether vegetable or animal, we cannot doubt.

One thing that is hard to reconcile to the view of their viability is their protean shape. Nothing could look more unlike one of the small unpigmented amœboid bodies inside the red blood-corpuscles than the large crescent with its bunch of pigment in the centre, and the ciliated body is wonderfully unlike both.

It seems probable that the crescentic form of this organism is more tenacious of life, has a greater power of resistance than the other forms. And this form appears in just those cases of malaria where quinine proves most inefficacious. It is possible also that this form may represent the adult organism from which the other forms may be produced, and quinine, while not acting destructively on the adult form, may prove destructive to spores or younger forms evolved from this. It is also possible to assume that the good effect of quinine in this condition may make itself felt by raising the powers of resistance of the tissue cells, particularly the red blood-corpuscles, enabling them to resist successfully the attack of the organism.

The various steps in the evolution of the organism have not been made out. Lavaran says that the free-moving cilium is the true organism, and that it attacks the corpuscles, while Marchiafava and Celli claim that the active agent is the amœboid organism. It is possible that there may be an earlier form than either of these. Marchiafava and Celli have described small, isolated masses in the interior of red corpuscles which are not larger than micrococci, and stain brilliantly with methylene-blue. I have seen similar bodies in numerous cases of intermittent fever, sometimes in considerable numbers, at others very few. They were never found in other cases than intermittent. Often club-shaped processes of the plasmodium will be found connected with the central mass by very fine filaments, and these may be mistaken for the small, round masses. It is possible, when the corpuscle contains numbers of these, that the whole may be connected by slender threads which elude observation, or the plasmodium itself may break up into these small masses. That there is some connection between them and the plasmodium is shown by the fact that they are always present together. It is also possible that they may represent the earliest form of the organism, and the plasmodia may develop from them.

Nothing definite is known as to the actual connection of all these various forms of the organism with each other. Until it can be isolated from the body and grown in suitable media outside of it, there can be nothing but mere speculation concerning this connection. All attempts to cultivate it outside of the body have failed. The organism is not a bacterium, and most probably cannot be cultivated in the same manner that bacteria are cultivated. Its whole morphology declares it rather to belong to the protozoa, and with every means at their command zoölogists have never succeeded in cultivating these as bacteria are cultivated, and as common as the protozoa are, the complete life history of few or no examples of the group has been made out.

The importance of these recent discoveries in malaria can hardly be overestimated. Not only is a new territory opened to the pathologist, but to the clinician the sure means is given, by a simple examination of the blood, of diagnosticating accurately the most complex, and sometimes most terrible, of diseases, and in which more depends on a speedy and certain diagnosis than in any other disease. Not only is he enabled to diagnosticate the disease as such, but in most cases the particular form.

PRIAPISM: ITS CAUSES AND TREATMENT, INCLUDING THE HISTORY OF A REMARKABLE CASE.

BY J. L. DAWSON, JR., M.D.,
OF CHARLESTON, S. C.

PERSISTENT erection of the penis is a trouble so rarely met with that our literature on the subject is very meagre. The journals, from time to time, report cases, from which most of our information is collated, and from which we must deduce most of our conclusions.

There seem to be three classes of causes: first, those due to traumatism, producing inflammation and lymph extravasation; secondly, those directly due to diseases of the nervous system; and thirdly, those due to nervous excitations of a reflex character.

Cases of injury to the penis during the act of copulation, and subsequent persistent erection of the organ, are often met with, and as frequently reported. Cases dependent upon diseases of the nervous system are exemplified in the persistent erections attending locomotor ataxia. Disease and injuries of the cerebellum and spinal cord are known to produce erections of a severe nature. I have seen sudden erections occur at birth in cases of breech delivery, as the head engaged in the superior pelvic strait, due, possibly, to pressure upon the cerebellum by the movable cranial bones. Again, local irritants, such as foreign bodies in the rectum, irritation of the prostate, and adherent prepuce, produce erections through the reflex nervous centres.

"Mr. Bryant[1] circumcised a boy, aged two years, who was suffering from an erection of the penis which his mother declared positively had existed from birth. He could pass his water freely, but the prepuce was long and adherent to the glans. When eleven months old he had tetanic fits, followed by wasting of his legs. The operation removed all symptoms." Some authors believe that effusion of blood into the corpora cavernosa may be caused by impeded return of the blood in persons suffering from leukæmia, in a way analogous to the hemorrhage from mucous membranes that occurs in that disease. "Dr. Salzer,[2] of Worms, narrates a case of priapism in a man aged forty-six, who awoke with his penis in a state of violent erection, which even the administration of chloroform did not allay. He considers this condition to be one of the symptoms, but a rare one, of leukæmia. The spleen was enlarged from attacks of ague."

On Sunday, August 28, 1886, I was called to see J. J., suffering from priapism. The patient was a healthy negro of about thirty-five years of age, a fisherman by occupation, and the father of several healthy children. He gave the following history: The previous week, from Monday night until Saturday morning, he had been shrimping, spending his nights in an open boat, and using a cast-net. On Saturday morning he reached the wharf at 5 o'clock, and, being very tired, he laid down in the open air and slept for an hour. He then went home and rested part of the day, but went out again in the evening. On retiring, at 11 P.M., he had connection with his wife. The act was not satisfactory. As he describes it, his emission was slight and rapid. He attributed this to exhaustion, and immediately went to sleep. He awoke at seven the next morning, with an erection more forcible than that caused by a distended bladder, to which he was accustomed. He got up and urinated without trouble, but his penis did not become flaccid. He returned to bed and again had connection with his wife. The act, he declares, was perfectly performed without uneasiness, but after ejaculation the organ remained in a state of erection, and began to pain him along the urethra in the perineum. He applied cold water and took a cold bath, but these having no effect, he wrapped the organ in crushed ice.

Still suffering, he summoned me to his aid, and when I saw him, at 12 M., the penis was firm, erect, and hot. The corpora cavernosa seemed to be the portions most involved in this turgescence, for the corpus spongiosum and glans were softer, and the prepuce could be readily drawn forward so as to cover the glans. I ordered hot fomentations to be applied, but they availed nothing. I again tried the ice bag, and ordered fifteen grains of potassium bromide every hour. This was continued during the day, but at my evening visit I found the organ in the same condition, the pain unabated. He slept at short intervals during the night, but was frequently awakened by pain, which was of a sharp, paroxysmal character, intensified by entanglement of the erect organ in the bedclothes. The day following he was put upon fifteen grains of chloral hydrate and thirty of potassium bromide every hour until six doses were taken. This giving no relief, in the afternoon I injected half a drachm of a four per cent. solution of muriate of cocaine into the urethra. After waiting a reasonable time, electricity was tried. The interrupted current was used, one pole being applied to the lumbar region, the other to the perineum. The poles were shifted from time to time, and the current sent directly through the organ, but it produced no relaxation whatsoever. I wished to try the continuous current, but could not obtain a battery at the time. A brisk cathartic was administered, and the following suppositories introduced into the urethra during the night: extract belladonnæ, grs. iij, extract opii grs. ij, ol. theobrom. q. s.; ft. in suppos. no. iii. The following morning the patient was suffering greatly, and had slept little. A half grain of sulphate of morphia was given hypodermatically, which had the effect of producing profound narcosis, but the organ persistently refused to become flaccid.

In the evening of this, the third day, as the man was still suffering, I determined to open the corpora cavernosa, and evacuate the blood, fearing that gangrene might ensue. With the assistance of Dr. P. G. de Saussure and Dr. J. J. Edwards, chloroform was administered and pushed to its utmost limit. The cavernous body of the right side was incised at the pubes, and a quantity of dark grumous blood evacuated. Although we extracted as much as we thought advisable, it had very little effect on the erect organ.

Having failed in every expedient, we determined to continue the bromides and watch the case. During the priapism there was no difficulty in the passage of the urine, the patient emptying his bladder easily. The erection continued for ten days, and nothing further was done beyond the application of tobacco poultices and the administration of stimulating enemata, which seemed to have little effect. The turgescence began to subside on the tenth day, and in four or five days the penis had gradually returned to its normal flaccidity.

Nearly two months have elapsed: the patient enjoys his usual degree of health, and has returned to his work, but he is unable to have an erection. He has attempted the act of copulation several times, but the penis remains flaccid, although he asserts that he has an orgasm with ejaculation.

Leukæmia may have been the cause in this case, as I had attended the patient with malarial fever some months previously; he was necessarily exposed to malarial miasm, spending his nights among the marshes along the coast. I had never examined his spleen physically, and did not take this disease into consideration during my attendance on the case.

Our treatment in these cases must be guided by the cause. Where the priapism supervenes upon injury, and is due to inflammatory deposits, antiphlogistics are, of course, indicated. When supervening upon nervous troubles directly, or by reflex stimulation, we must use sedatives, and the bromides are supposed to meet this indication most promptly. Opium and its alkaloids are also of great value.

Locally, hot fomentations, ice, anodyne applications, anodyne enemata and suppositories have all been more or less beneficial. The overloaded cavernous bodies may be opened and the blood evacuated when everything else has failed; but this should be a last resort, as the injury to the part is intensified, and inflammation, however slight, will only bring an increased supply of blood to the organ. If we believe the priapism to be a symptom of leukæmia, then large doses of quinine in combination with iron should be of benefit.

The disease seems to run its course occasionally in spite of everything we can do. Its tendency is to recovery, but it may threaten mortification. Hunter says he once saw a case of this kind in a dog, in which the erection refused to subside, and the penis mortified and dropped off. There is one case on record of injury to the penis during sexual intercourse, in which death ensued two weeks after the commencement of the priapism, but to what the immediate cause of death was attributed is not stated.

REPORT OF CASES ILLUSTRATING THE GREAT CONTAGIOUSNESS OF SCARLET FEVER.

BY BOARDMAN REED, M.D.,

OF ATLANTIC CITY, N. J., FORMERLY PHYSICIAN TO THE MERCER MEMORIAL HOUSE FOR INVALID WOMEN.

THE science of medicine is not yet completed, and it is the bounden duty of every physician to report cases which may assist in the determination of mooted questions. The paper read by Dr. Arthur V. Meigs, on "The Contagiousness of Scarlet Fever," at a recent meeting of the Philadelphia County Medical Society, raised a question of the utmost practical importance. It was an able and elaborate presentation of views which have long been held by some experienced physicians—views which from time to time have been set forth with more or less cogency in medical literature.

Dr. Meigs contends that scarlet fever is by no means so contagious "as is commonly reported, and very much less so than measles and whooping-cough, and some of the other common contagious maladies." The ten cases cited by him certainly show that the contagium of scarlet fever is less volatile than that of measles and whooping-cough, and less likely to pervade an entire house. In one of his cases, moreover, there was an exposure of two children to the disease for some hours after the rash appeared, without its being taken. I have seen similar cases where one child in a family having been taken with scarlet fever, the other children, who had been with the sick one till shortly after the rash appeared, were isolated and kept in another part of the house till a month or more after convalescence was established, and then allowed to associate again with the convalescent without contracting the disease. In these cases, however, the greatest pains were taken to destroy or thoroughly disinfect every article of every description which had been in the sick-room. The convalescent children were bathed, their heads shampooed, and they themselves taken daily out into the air for a week before being permitted to mingle again with the other children. Without these extraordinary precautions my experience teaches that even a month's separation is no guarantee against the contagion.

Most of the authorities on the diseases of children refer particularly to the lack of volatility of the scarlet fever poison. It is an established fact that it is usually necessary to be quite near a case of the disease in order to contract it. It is getting to be pretty well settled, also, that scarlet fever is less contagious previous to the coming out of the rash than afterward. Probably the same is true of most of the eruptive fevers.

Granting all this, and granting, also, that adults rarely take scarlet fever, while the older children of a family sometimes—though certainly very exceptionally—escape after complete exposure during the height or decline of an attack, I must still insist on considering this one of the most contagious, as well as the most treacherous and dangerous of the exanthemata. What its contagious principle lacks in volatility it makes up in persistency and indestructibility. It has been known to remain for years in articles of clothing without losing its virulence. Even the comparative insusceptibility of the middle period of life is not a sure protection against it, provided the exposure is frequent or long continued.

The following case strikingly illustrates the certain contagiousness of scarlet fever when neither isolation nor other preventive measures are practised.

CASE I.—In the summer of 1879, a few cases of scarlatina occurred in one of the public schools of Atlantic City. In a poor family, consisting of father, mother, and six children, the oldest, a girl of ten years, contracted the disease. She was put to bed in the upper room of a two-roomed dwelling in which the entire family slept. One after another, at intervals of two to five days, all the children were attacked. Finally the mother, who had nursed them night and day, contracted the fever. The father, who had previously been out at work during the day, though sleeping in the one bedroom with the sick ones at night, escaped till the last; but having then to take the mother's place as nurse, and hold one or other of the sick children on his lap, he could not longer resist the concentrated contagion at such close quarters, and himself came down with the disease. None of the cases was malignant, and all recovered.

The following is one of several cases closely resembling each other, which have occurred in my practice.

CASE II.—One of a family of two children had scarlet fever in Philadelphia. The other child was kept away until an entire month after convalescence was established. Then both children were brought to a boarding-house in Atlantic City, and allowed to occupy the same room. Within a few days the other child was attacked, when, as is the custom here, the entire party was obliged to remove at once to a private cottage. The greatest care was used in disinfection, and the disease did not spread any further.

Owing to the regulation enforced by all hotel proprietors at this resort, that guests who develop any contagious disease must be immediately removed, I have never, except in the following instances, known

any such diseases to be contracted from other cases in a hotel here. Whooping cough cases are sometimes permitted to remain in the smaller boarding-houses, but never in the hotels or more important hostelries. It is significant as to the contagiousness of scarlet fever that these only exceptions (described below) were of that disease.

CASE III.—A child brought from a neighboring city to a hotel here developed a severe and typical attack of scarlet fever on the night of its arrival. I saw it the next morning, and advised that it be immediately quarantined in a cottage. Instead, the family took it home, where it died the next day. The room occupied by it was disinfected, but perhaps not with sufficient thoroughness. Some two weeks later a child arrived from another city, and by accident was assigned to the same room. Within twenty-four hours it was seized with high fever, rapid pulse, vomiting, and acute inflammation of the fauces. No rash had yet appeared when my visit was made; but, anticipating scarlet fever, I again advised removal to a cottage. The parents, against my protest, returned home with the child. A diagnosis of diphtheria was there made, and death resulted in two or three days. There had been no diphtheria in the house, and, considering the circumstances, it seems to me at least probable that this was a case of scarlatina without rash. The room was now thoroughly disinfected, and no other children were permitted to occupy it for several months. About the same time a family with two children were occupying a room on the same floor, and nearly opposite the one just referred to. Within a week after the last case mentioned, one of these children was attacked with scarlet fever, and the family then promptly removed to a cottage. The child did well, recovering in due time. The other child occupied a different room after the transfer, but by the end of a week was taken with slight fever, and sore throat, evidently scarlatinous, but had no rash. There had been no other cases in the hotel, and, though this was several years ago, there have not been, to my knowledge, any cases in it since, either of diphtheria or of scarlet fever.

In view of the above facts, I submit that physicians cannot be too careful in guarding against the spread of scarlet fever. On account of its frequently malignant and deadly character, as well as the serious complications and sequelæ which so often afflict children that do not die of it outright, it is certainly to be dreaded more than any other disease of childhood. Therefore, admitting that it is somewhat less contagious upon slight exposure, or at a distance, than some other diseases, let us nevertheless inculcate greater rather than less stringency in quarantining against it.

A CASE OF POST-PUERPERAL HYPERPYREXIA, WITH A TEMPERATURE OF 109.4°; TREATED BY COOL SALT-WATER BATHS; RECOVERY.

EVER since the introduction of the clinical use of the thermometer, the question of the extreme limit of bodily temperature compatible with life has attracted attention. Liebermeister has made many researches upon the lower animals, mammifers and birds, and it appears that these animals infallibly die when their temperature has reached a point 10° or 12° F. higher than their normal. He remarks, in accordance with Bærensprung, that the maximum of bodily heat observed in human beings who have recovered is 108.5° F., and believes that the absence of a higher temperature demonstrates the impossibility of the preservation of life beyond that term. Another investigator, Weikart, declares that at 109° F., blood decomposes and coagulates. Wunderlich also believed that a temperature exceeding 108° F., necessarily caused death. Nevertheless, it seems that there are rare exceptions, under certain conditions, to this general rule. For instance, Hirtz[1] affirms that in the clinique at Strasburg a temperature of 111.2° F. was observed at the culminating point of an access of simple tertiary fever of a benign character. But he does not definitely state by direct assertion that the patient ultimately recovered.

It has recently fallen to my lot to observe a case of extreme hyperpyrexia which developed under special conditions. The following are the principal facts relating to it, which were gathered with the utmost care and exactness.

Mrs. H., passenger on the steamship "Marseille," sailing from Antwerp to New Orleans, gave birth, on August 24th, to her first child, which was well developed and born at the termination of the normal term of gestation. The confinement was natural, but the posterior wall of the vagina was slightly torn in its lower portion during the passage of the cephalic extremity of the fœtus. The delivery was slow, lasting more than an hour, and it is probable that a small portion of the aminos was left in the uterine cavity after the placenta was extracted. There was very little hemorrhage, but during the succeeding days a fetid sanious discharge escaped from the vulva in considerable quantity. During the first four days after the *accouchement* there was complete absence of fever, and of every subjective morbid symptom. The parturient occupied a bed in the hospital of the ship, where the sanitary conditions were deplorable. No ventilation worthy of the name, an insupportable, stifling heat, and cleanness and especially asepsis more than problematic; such were some of the conditions in which the *accouchée* was placed.

Until the 28th of August, the temperature of the parturient had not exceeded the normal. Even on the morning of that day it was still 100°, but at evening it had risen to 102.2°. This was the fourth day after confinement. The general condition of the patient was satisfactory. Owing to abundant perspiration, the entire surface of her body and limbs was covered with abundant sudamina.

August 29.—Fifth day; morning temperature taken in the rectum, 104°. The vaginal discharge still abundant and fetid, notwithstanding injections of carbolized water into the uterine cavity twice daily. At 4 P.M. I found her with the extraordinary rectal

[1] Dictionaire de méd. et de Chir. pratiques: Art. Chaleur.

temperature of 109.4° F. Surprised by such a high point and desirous of removing all doubt of its precision, I took the temperature a second time with the same result; I also took the axillary temperature, which was 109.2°. In view of the urgent necessity of reducing the central temperature of the patient without delay, I at once instituted the antipyretic treatment *par excellence*, the employment of cool or cold water. At first, lotions with sea water at 82° F. were administered over the entire surface of the body during an hour. This brought the rectal temperature to 107.6°. Then the patient was placed in a bath of sea water also at 82°, and remained there during another hour. After the first half hour the rectal temperature fell to 102.2°, and at the termination of the bath it was at 100.4°. The pulse, before the bath, was 154, afterward 120. A cathartic (an ounce of magnesia sulph.) had been administered as soon as her high temperature was discovered, and after the bath she was given a few grains of sulph. quinine. This was all the treatment employed to combat the fever, except that she was not returned to the hospital, where the heat was very great, but was placed in a stateroom on deck.

During the whole of the fever, the patient preserved the entire use of her mental faculties and a large proportion of her strength. No morbid phenomena, general or local, presented themselves, other than those already mentioned.

30th.—Great improvement in the patient. Continuation of the sulph. of quinine in doses of ten grains twice daily. Rectal temperature: A.M. 101.3°, P.M. 102.2°. Late in the afternoon, another bath with sea water at 84° caused the rectal temperature to fall to 100.4°.

During the following days the fever gradually diminished up to the arrival of the steamer at New Orleans, when the patient was transferred to Charity Hospital. She remained there nearly three weeks without presenting any new symptoms, and left the hospital September 23d after complete recovery.

It is interesting to observe that upon the same day that the patient showed her maximum temperature, the heat of the atmosphere in the hospital where she was lying was very great, being, by careful observation, *not less than* 91.4°. This was the degree of heat in that part of the ship during several successive days at this period, and I am inclined to think that this excessive heat of the *milieu ambiant* had much to do with the intensity of the fever in the case in point. This would explain, to a certain extent, the ease with which the patient's temperature was lowered, and the improvement which immediately succeeded her removal to another room where the heat was less.

One might object to the report of this case by remarking that the thermometer employed in this instance might not be exact; in other terms, that there might have been an instrumental or thermometrical error. I would respond to this objection by the statement that the thermometer employed in this case is the same that I used for three years in the Paris hospitals, but in order to remove all doubt as to its present precision, I had it tested, after the voyage, in the laboratory of General Pathology of the Faculty of Medicine of Paris, and it was found to be exact.

The ultimate recovery of fever cases having had a central temperature of 109.4° is extremely rare. It is on this account that this observation is worthy of publication.

RECOVERY FROM AN OVERDOSE OF MERCURIC CHLORIDE.

BY S. T. ARMSTRONG, M.D.,
PASSED ASSISTANT SURGEON U. S. MARINE HOSPITAL SERVICE.

THE following case seems worthy of record as an instance of recovery consequent upon an extremely large dose of mercuric chloride:

John McDonald, aged thirty-five years, was employed temporarily as a hospital orderly, though by occupation a sailor, and endowed with the virtues and vices common to men of that pursuit. Principal among the latter characteristics was an overpowering affection for alcohol—in any form. Once, while in the navy, he drank a tin-cup full of an alcoholic solution of shellac, and without any subsequent physical penalty, save great temporary discomfort.

On November 1, 1886, during the temporary absence of the physician and steward, the subject of this history, for some time deprived of any opportunity for alcoholic indulgence, and having no wherewithal to obtain liquor, entered the hospital pharmacy, and finding the dispensary bottle of alcohol, containing spirits 95 per cent. proof, took a drink of about thirty cubic centimetres of the liquor.

The result was so satisfactory to him that, in a short time, he repeated the potion. On attempting a third potation, he took from the drug shelf a bottle, of similar size and adjoining the alcohol bottle, containing a solution of mercuric chloride, 100 grammes in 500 grammes of alcohol, used for quickly preparing ward solutions of bichloride of mercury. He poured out, he judged, the same quantity of the liquor as before—a quantity that contained six grammes (ninety grains) of mercuric chloride—and drank it at a gulp. As soon as it passed his throat, he knew from the burning sensation, that he had taken something wrong.

Almost instantly violent cramping and vomiting occurred, soon augmented by free purging and micturition. The hospital steward returning within an hour after the poison was swallowed, found the man coiled up on the grass, and learning from him that he had taken something from the medicine case, gave him, on general principles, a dose of sweet oil. I saw the man shortly afterward. His face was pale, eyes sunken, expression anxious, voice stridulous—he spoke with difficulty; heart's action feeble and rapid, skin cold. Insatiable thirst, and continued vomiting of the few drops of water he momentarily swallowed. Tormina and tenesmus, with occasional evacuations of a small quantity of intestinal mucus. Copious micturition.

To counteract the collapse a hypodermatic injection of atropia sulphate 0.002 gramme was given, and the patient put to bed.

An inspection of the pharmacy was made, and a graduate found containing a white deposit on its

side; an examination soon showed this to be mercuric chloride, and a glance at the medicine shelf explained the source of his potations. In consideration of the potency of the poison, and the condition of the patient, the case was prejudged hopeless. Reaction, however, followed the hypodermatic, he became stronger during the night, and though very weak the next morning, gave promise of recovery. The subsequent history of the case is unimportant; intense salivation occurred, which was treated as usual, and the case discharged, recovered, on November 11th.

It is considered that the alcohol (60 c. c.) first drank had dehydrated the mucous membrane of the œsophagus and stomach, rendering absorption slow, and the excessive dose of the bichloride proved so irritating that he vomited most of it.

MEDICAL PROGRESS.

THALLIN IN TYPHOID FEVER.—The introduction of such drugs as kairin, thallin, and antipyrin has somewhat diverted attention from a very powerful antipyretic agent, viz., thallin. PROF. EHRLICH lately presented to the Clinical Society of Berlin the results of some researches he has been making with this last-named agent, especially in the treatment of typhoid fever (*Münch Med. Woch.*, No. 47). From experiment, he had found that after administering the drug to animals it was not retained in the nerve centres, but mostly in the fatty tissue of the body. He also found that there was a marked difference in toxic action, according as to whether it was administered by the mouth or subcutaneously, the greater inertness of its effect in the former case being attributable to the hindrance to absorption from the presence of intestinal contents. The lesions induced by a toxic dose comprised fatty degeneration of the kidneys, necrosis of the salivary glands and pancreas, and hemorrhagic infarcts in the renal pyramids. The chief action of thallin is antipyretic, but it is capable, also, of moderating inflammation. As regards typhoid fever, it was administered by Ehrlich in two different ways. The first plan consisted in commencing with doses of 0.06 gramme every hour, and reducing the dose to the minimum required to give any effect. The other plan was to commence with a minimum dose, and increase it until an effect was produced, and then to continue the prescription at the dose thus attained. The action of thallin is especially noticeable in its effects on the sensorium and general condition of the patient, who presents the appearance of convalescence, whilst the splenic swelling and roseola are still present; and if the drug be discontinued the temperature will rise again. It is not therefore surprising to learn that, whereas of twenty eight cases treated by bathing, the average stay in hospital was thirty-seven days; of seven cases treated by thallin (minimum doses), the duration of treatment was forty-seven days; and cases on a scale of progressive doses, thirty-eight days. However, Professor Ehrlich claims advantages for the drug in the absolute control it exerts over the pyrexia, and the sense of well-being enjoyed by the patient. There were no intestinal hemorrhages in these cases, and no instance of perforation. The kidneys were not affected, but sequelæ in the form of hyperamia and œdematous swellings seemed due to the use of the drug. It was not thought that thallin had any specific action against the typhoid bacillus, but it did seem to limit the degree of intestinal ulceration. Professor Ehrlich considers it to be on a level with the bath treatment. DR. FRANKEL pointed out that if the statement were correct that thallin is not found in the nerve centres, its action in reducing temperature was rather inexplicable. He had exhibited it in increasing doses, but could not say that the patients experienced any special benefit attributable to the diminished fever. DR. GUTTMAN had not been favorably impressed by its use, and had noted the production of rigors.—*Lancet*, December 25, 1886.

SURGICAL TREATMENT OF PERITONITIS.—TRUC, of Paris, in the *Revue de Chirurgie*, No. 11, 1886, states the indications for surgical interference in peritonitis to be as follows:

The presence of grave general or functional disease dependent directly upon peritoneal inflammation, and seriously threatening the life of the patient.

Encysted peritonitis demands the evacuation of the contents of the cyst and its thorough disinfection.

In diffuse forms, if the cause be known, treatment should be directed against it; if it be not known, a thorough exploratory laparotomy should be made, and the case treated in accordance with the indications found.

Collapse and hyperpyrexia are contraindications to operation.

A BEVERAGE USED IN BRIGHT'S DISEASE.—PROFESSOR SEMMOLA, of Naples, has recommended the following to be taken as a beverage:

Sodii iodid.	gr. xv.
Sodii phosphat.	gr. xxx.
Sodii chlorid.	ʒjss.
Aquæ potabilis	Oj.

This may be drunk mixed with milk, if the taste is objectionable.—*Bulletin Générale de Thérapeutique*, November 30, 1886.

STUDIES IN THE ELIMINATION OF POISONS.—SANQUIRICO, of Siena, has investigated the elimination of poison by the kidneys, and the means of increasing such elimination. His studies were based upon the well-known facts that the organism often rids itself of injurious substances by the kidneys, and that the vascular system has the power, without undergoing extensive alterations, of permitting the exosmosis of fluids which had been injected into the body to the extent of eight per cent. of the body-weight.

The introduction of neutral fluids increases the tension of bloodvessels, and this tension is relieved by the organs of elimination.

Taking advantage of these laws of the economy the investigator experimented with chloral and aconitine in the following manner: A minimum fatal dose was given to an animal, and on the appearance of the first symptoms of impending death a three-quarter per cent. solution of chloride of sodium was injected in the subcutaneous tissues of the neck in amount eight per cent. of the weight of the animal; in the case of poisons the

action of which is immediate, the injection was made as soon as the poison had been taken.

With alcohol, strychnia, and chloral profuse secretion of urine occurred, and the animal recovered; in poisoning with aconitine the quantity of urine was often small, and the animals perished before elimination could be established; when the urinary secretion gradually increased the animal was often saved. The poisons used were found in the urine of animals which recovered.

Curarine, morphine, and hypnone were given, and ten per cent. of the body-weight in neutral solution was used with entirely negative result; the secretion of urine was never established after the administration of the poison.—*Centralblatt für die medicinischen Wissenschaften*, December 18, 1886.

Experiments in Trap Siphonage at the Navy Museum.—Repeated experiments on trap siphonage have shown beyond question that the ventilation of soil-pipes and traps is a safeguard against the entrance of sewer gas into dwellings except in unusual contingencies, provided the general plan of the drainage and sewerage is correct, and the workmanship good. The experiments at the Navy Museum in Washington have confirmed the results of those reported to the National Board of Health by Philbrick and Bowditch, and are stated in the following terms:

1. The seals of ventilated traps are safe against siphonage and back pressure.

2. The seals of unventilated traps are never safe from siphon action or back pressure, except in deduction four.

3. The vertical vent should be three inches, with a four-inch soil-pipe.

4. Traps connected on a horizontal pipe and fixtures discharging on the same level into horizontal pipe, apparently have no effect on unventilated traps.

5. All varieties of non-mechanical traps are more easily affected by back pressure than by siphonage.

6. The ball-traps were not affected by back pressure, but by siphonage.

7. The Sanitas trap withstood siphon action better than any of the patent traps, but was easily affected by back pressure.

8. The sewer air is more liable to enter unawares by back pressure through the seal of the trap, because the seal remains unbroken.

9. Difference in friction of iron and lead pipes made no apparent difference in the effect on the traps.

We are left in the dark, however, as to the precise nature of the unusual contingencies under which it is admitted that ventilated traps may be siphoned out and the emanations from the sewers enter houses; and Putnam and Waring think that they have shown that the so-called unusual conditions may occur where not in the least suspected, although a patent trap and water-closet intended to meet these "unusual contingencies" might perhaps serve as a bias against entirely unprejudiced judgments in the case.

It is true, however, that the approved methods of plumbing are now so costly as to make them practically unattainable to many householders, and that, outside of a very simple system of plumbing for moderate-sized houses, it is difficult to know with certainty what is safe and what not. The Museum of Hygiene, under the Navy Department, has an excellent opportunity to show just what the conditions are by which water-closets and soil-pipes inside a house may be made free from danger, and, it is to be hoped, that this will be done, no matter what the cost of time or money. If plumbing can be simplified and cheapened at the same time, the benefit to society will be incalculable.

Urine.—The following is a summary of the investigations made in the study of the urine during the past year, as given by the *British Medical Journal* of December 25, 1886. The acid reaction of urine is due to the excess of acid over normal phosphates. The ratio of the phosphoric anhydride combined as normal phosphate to that as acid phosphate is the following: evening urine, 91 : 100; night urine, 56 : 100; morning urine, 58 : 100; or for the urine of the twenty-four hours, as 69 : 100.

Hypobromite solutions do not keep well, and accordingly Lunge has recommended the use of A. Frank's bromum solidificatum. The solution is thus prepared: 400 grammes of caustic soda are dissolved in a litre of water and kept in a stoppered bottle. To 100 cubic centimetres of this solution about 100 grammes of bromine, that is to say, 10 centimetres of the stick of the brom. solid., are added. When the stick is decolorized the solution can be employed.

On the relationship of the formation of urea and uric acid to the secretion of bile some interesting papers by Noel Paton will be found in this year's *Journal*, to which we must direct the reader. Suffice it here to say that the author establishes a direct relationship between the urea formation and the biliary secretion.

Albuminuria.—The temperature, according to Loewy, exercises a marked influence on the composition of filtered liquids. The quantity of the filtrate increases with the elevation of temperature. He agrees with Senator in regarding the albuminuria occurring in certain febrile conditions as due to the elevation of temperature.

The effect of compression of the thorax has been studied by Schreiber, according to whom a slight temporary albuminuria is the result, its degree being increased with the duration of the compression. Serum albumin and globulin were the albumins met with. Schreiber concludes that dyspnœa was not the cause of the albuminuria, but that the factors are: the diminution of the difference of pressure normally existing between the alveolar capillaries of the lung and the left ventricle; the diminished calibre of the pulmonary vessels, and the diminished extent of the respiratory excursions. A stasis in the pulmonary circulation is thus produced which is rapidly propagated to the renal capillaries, with consequent filtration of albumen. In young subjects (eleven to fifteen years) a thoracic compression lasting half a minute has sufficed to cause the appearance of albuminuria, of which there were no traces an hour subsequently.

Biliary Urine.—Oliver has proposed the following delicate test for the biliary acids. The solution is prepared thus: peptone in powder, 1.8 grammes; salicylic acid, 0.24 gramme; acetic acid, 60 drops; distilled water, 240 cubic centimetres. One part of urine containing biliary salts in a pathological proportion when

added to three parts of this reagent causes the appearance of an opalescence, which disappears on the addition of one or two drops of acetic acid, but not on boiling. The urine should be transparent; if it contains urates in excess it should be warmed; if muddy from phosphates it is to be slightly acidified with citric acid, or filtered; if blood or albumen is present it is to be boiled and then filtered; and it is further advisable to reduce the density of the urine to 1.008.

Sugar.—Two delicate tests have been proposed. A solution of hydrochloride of phenylhydrazine, containing sodic acetate, gives a yellow crystalline precipitate. By this test sugar is never found in normal urine. If much albumen is present it should first be separated. A still more delicate test is the following, by means of which sugar can always be detected, even in normal urine. A small quantity of the saccharine solution is mixed with two drops of an alcoholic solution of naphthol or thymol, and an excess of strong sulphuric acid added; a deep coloration is produced, violet with the former and red with the latter. The test is of especial value for microchemical examinations.

Pigments.—The physician's attention should be directed solely to two urinary pigments, urobilin and indican, as the existence of other pigments is doubtful, and their significance equivocal. Cervesata has published some interesting conclusions as to urinary indican, of which we shall briefly summarize the chief. Normal urine contains uro-indican, whose artificial or spontaneous decomposition gives rise to indigo. To detect the indigo blue, it suffices in most cases to employ sulphuric acid and chloroform; but it is always useful to treat the urine previously with basic acetate of lead, particularly when it is scanty, dense, and high-colored. The sulphuric acid is preferable to the hydrochloric, because the reaction occurs more readily and more markedly, and is less liable to error. Vierordt's spectrometric method is recommended for its determination. In individuals in good health the indigo is found in very small amount, increasing, however, under a meat diet, but to a greater extent if aromatic compounds are administered; fasting, on the other hand, causes its diminution. Its elimination is greatly increased in diseases in which inanition and marked tissue-waste are prominent factors; also in diseases of the abdominal organs, particularly of the intestine; in many nervous affections, in splenic anæmia, renal cirrhosis, diabetes, and chronic lead poisoning. On the other hand, its elimination is very slight in fevers, parenchymatous nephritis, chlorosis, scrofula, advanced phthisis, catarrhal jaundice, hepatic cirrhosis, and ovarian tumors. The variations in its elimination are probably to be attributed to nervous modifications of the pancreatic secretion.

Aromatic Constituents.—Baumann has tried to determine the relationship between the putrid fermentations occurring in the intestine, and the formation of the sulphovinic and oxy-acids. From experiments on a patient with intestinal fistula he was led to conclude that when the putrefaction diminished in the intestine, as after the administration of calomel, the sulphovinic acids diminished equally in the urine.

A concentrated solution of picric acid produces a slight crystalline sediment in normal urine after an hour or two. Jaffé finds this to be partly uric acid and partly a double salt of kreatinin picrate with potassic picrate. It forms, indeed, a delicate test for kreatinin, giving a deep-red color with dilute solutions in the cold.

Alkaloids.—To detect these the reagent employed is thus prepared: iodine, 8; potassic iodide, 10; water, 10. Cool the urine to 0° C., after adding a few drops of the reagent: then concentrate a bright light by means of a lens on the urine in a test tube placed against a dark background. The green fluorescence is readily seen. It can thus be shown that the proportion of alkaloids in the urine passed during the eight hours after waking is five times as great as in the urine of the rest of the day.

Toxicity.—Bouchard has continued his researches as to the toxicity of normal urine. Man, even in a normal condition, is constantly destroying and excreting poisons either introduced into or formed in the organism, and the urine is one of the chief sources of elimination.

After an intravenous injection of normal urine, there is contraction of the pupils followed by quickened shallow respirations and muscular weakness. The urinary secretion augments and the temperature falls. Death happens generally without convulsions, the animal dying most frequently in a state of coma. The quantity of normal urine necessary to destroy the life of a kilo of living tissue is very variable, oscillating between 10 cubic centimetres and 122 cubic centimetres per kilo, but 45 cubic centimetres may be taken as the mean in an adult. A man requires about two and one-sixth days to fabricate the quantity of urinary poison capable of poisoning himself, a coefficient, it may be said, which varies little in health, but greatly in disease.

The urine secreted during sleep is less toxic than that of the waking period. The character of the poison eliminated in the two periods also differs greatly, that of the waking period being narcotic in its properties, and that of sleep being convulsive. During the former, therefore, the body produces a substance which, accumulated, will induce sleep; during sleep, on the other hand, it elaborates a convulsive principle, which, when it accumulates, would tend to produce muscular irritation and provoke wakefulness. The variations in the toxicity depend especially on the greater or less intensity of the oxidations; with increased muscular activity, for example, during which more oxygen is consumed, the toxicity is lessened.

Feltz has experimented with febrile urine, and he finds that it is much more toxic in its properties; and, further, that there is no proportional relation between the density of the urine and its toxicity, as is the case with normal urine. There must, therefore, be other toxic agents in febrile, than are to be found in normal urine.

According to Lépine and Aubert, the special toxicity of febrile urine seems to be due to its organic rather than its saline constituents, as has been affirmed by some authorities; and, contrary to Bouchard and Pouchet, Villiers finds that normal urine never contains alkaloids, although these were present when the patient was suffering from febrile or inflammatory affections. Rovighi, again, like Feltz and Ritter, concludes from his experiments that uræmia is essentially determined by the salts of potassium, and that the uræmic convulsions are caused by an accumulation in the blood of inorganic salts, and more especially of those of potash.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance . . . . . $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, JANUARY 15, 1887.

FORMS OF ALBUMINURIA NOT DANGEROUS TO LIFE

In this age of refinement in diagnosis we are apt to place too much stress on some special symptom to the neglect of the general features of a case. Thus, in the hands of many physicians the stethoscope has led to error when the presence of a murmur has been regarded as proof of the existence of heart disease. So also albumen in the urine has for years been considered by the profession and the public as an occurrence of the gravest moment, indicating serious, if not irreparable, disease of the kidneys. In *The American Journal of the Medical Sciences* for January, 1887, Grainger Stewart has a very timely article "On Some Forms of Albuminuria not Dangerous to Life," from which we may derive several important lessons. He does not consider accidental albuminuria, due to admixture of the urine with blood or pus, nor the febrile form, nor that due to passive congestion. Four categories are defined, the cases in which, though varying greatly, may with advantage be distinguished from each other, viz., paroxysmal albuminuria; dietetic albuminuria; albuminuria from muscular exertion, and simple persistent albuminuria.

Paroxysmal or intermittent albuminuria is characterized by the sudden occurrence of albumen in the urine, often in large amount, with numerous tube casts, the process lasting a variable time, perhaps only a few days and occurring at intervals without any appreciable cause. This form is most commonly met with in young adults who are the subjects of some constitutional taint, and the attacks are apt to be brought on by cold or exposure, and by errors in diet. It has close relationships to intermittent hæmoglobinuria, as very clearly pointed out by Ralfe in the *British Medical Journal* of November 27, 1886. In fact, the attacks may alternate, and this writer brings forward evidence to show that "functional albuminuria is only a minor manifestation of hæmoglobinuria and that the two conditions may merge one into the other." Both conditions are induced by increased destruction of blood-corpuscles—hæmolysis—probably in the liver. The explanations offered of the process are purely hypothetical, but it is satisfactory to learn that the attacks do not prove permanently injurious. Stewart recommends chloride of ammonium as a suitable remedy, while Ralfe relies chiefly upon arsenic, which seems to have the power of lessening the hæmolytic action of the liver and at the same time strengthening the resisting powers of the corpuscles.

Of dietetic albuminuria, which is more common, the writer gives several very instructive examples and recognizes three factors as possible existing causes: First, the use of certain kinds of food; second, the entrance of food (of any kind) into the stomach; third, one or both of these in association with other influences, such as exercise or the time of day. A most curious fact is the appearance of albumen immediately after taking food into the stomach, the nature of the diet having little or no influence. In such instances the time which elapses between the ingestion of the food and the appearance of the albumen is so short that we must suspect a reflex vascular influence. In other cases the increase in the saline constituents of the blood after a meal may increase the diffusibility of the albumens and permit of their filtration in small amounts through the capillaries of the glomeruli.

Albuminuria following muscular exertion has long been recognized, and of late years several important memoirs have been written on the subject. Stewart reports two cases very fully in which a careful study excluded all causal conditions save exercise. The mere fact of rising seems to have an influence in inducing the albuminuria, for in his first case neither exercise in bed nor massage caused any change in the urine, while the change from the recumbent to the erect posture was invariably followed by the onset of albumen. In the state of our present knowledge we cannot give a satisfactory explanation of these cases, but it is very important to recognize their existence. In treating such cases rest and a careful diet will usually suffice to remove the condition, which is usually transitory. The use of ergot and belladonna is suggested.

Cases of the fourth category, simple persistent albuminuria, are more rare and the condition is much more difficult to separate from one of positive renal disease. The principal features of these cases are the continued presence of albumen, without tube casts, and without cardio-vascular changes,

or signs pointing to subacute nephritis. The health may not be seriously impaired for years, but the prognosis in these cases is more serious as the condition may culminate in organic disease. In distinguishing between the functional and organic cases Stewart lays stress upon the quantity of urea, the presence or absence of tube casts, and the state of the cardio-vascular system. In the fourth category, he says: "So long as the solids are in normal quantity and the vascular changes do not manifest themselves, we may speak hopefully even in such cases."

This writer gives a more favorable opinion of these cases than has hitherto been expressed, but we feel certain that it will be justified by future experience. A very large amount of mental worry and suffering is annually caused by the widespread belief that the presence of albumen in the urine is an indication of the gravest character, and by too many, both lay and medical, the condition is regarded as identical with Bright's disease. Prof. Stewart's article will do incalculable good in helping physicians to discriminate between the non-dangerous and the serious forms of albuminuria.

THE TREATMENT OF VARICOSE VEINS.

IN THE MEDICAL NEWS for September 11, 1886, we directed attention to the operation of excision in the treatment of varicose veins. The favorable opinion of this operation was supported by a letter from DR. S. J. RADCLIFFE, published in THE NEWS for September 25, in which a report was given of Mr. Clutton's success by this method in St. Thomas's Hospital, London. We may add that FRY has also employed this method with great success, and has recorded six such cases in the *British Medical Journal*, for September 5, 1885; while LE BRUN reports, in the *Journal Méd. de Bruxelles*, for March and April, 1885, twenty-one such operations without a single mishap. These results certainly indicate that excision for varicose veins is an excellent operation, and justify the opinion that it is simple, safe, and almost sure to effect a cure.

The plan of injecting into varicose veins various coagulating substances still holds its ground, however, and may be rationally adopted in cases in which either the patient or the surgeon does not wish to face a cutting operation. Very recently, STEVENSON, in *The Lancet*, for October 23, 1886, reports eight cases treated with perfectly satisfactory results by injection of pure carbolic acid, as recommended by Watson Cheyne. The circulation is controlled by the Esmarch tube, applied round the thigh, while the patient stands, first with a few turns just tight enough to occlude the veins, and then firmly enough to cut off all the circulation. One minim of pure carbolic acid is then injected at a number of points, about an inch and a half apart, and cotton and collodion are applied over the punctures. The Esmarch tube is not removed until fifteen minutes after the completion of the last injection, and then the circulation is permitted to return only by very slow degrees. This is to avoid the danger of an embolus being swept into the general bloodvessel system. In addition, the patient is required to keep his bed for about a week.

By this means excellent results have been obtained in the treatment of varicose veins, although abscesses sometimes form at the seat of injection. Stevenson found this to occur in about ten per cent. of the punctures, but the abscesses were not larger than a pea, and they were painless.

In the *Medical Record*, for December 12, 1885, WEBER reported a successful treatment of varicosity of the saphenous vein by means of injection of four drops of pure carbolic acid at four different points, while the vein was compressed above and below the part injected until a coagulum was formed in it.

It appears, then, that the operation of excision of varicose veins has not entirely supplanted the method of coagulating injections, and it probably never will do so, since circumstances altogether unconnected with timidity on the part of the patient, or conservatism on the part of the surgeon, must not rarely debar the former procedure. Such being the case, we think the injection of carbolic acid, in the prudent manner suggested by Cheyne, is one of the safest and best ways of treating this frequent and troublesome disorder.

THE CURETTE AS AN ABORTIFACIENT

AT a recent meeting of the Association of Physicians in St. Petersburg, DR. WEIDEMANN advocated the use of the curette in removing the fecundated ovum, when the production of abortion is imperatively demanded before the third month of gestation, as it may be not infrequently, especially in cases of exaggerated hyperemesis.

The arguments brought forward in support of the claim that this method is preferable to any other are forcible. The fœtus with its enveloping membranes, during the first three months of pregnancy, forms a polypoid tumor within the uterus, the attachment of which is at the seat of the placenta, and is quite firm, while the membranes are delicate and easily ruptured; if, therefore, as is often the case in early abortion, the fœtus alone is expelled, leaving behind its shell and the placenta, their subsequent decomposition is likely to lead to serious septic infection. With the curette the removal of the entire ovum with the placenta may be accomplished with certainty, avoiding the risks of the development of septicæmia, and, by the rapidity of the operation, preventing any excessive hemorrhage, which is often

an alarming complication in those cases in which, the expulsion of the ovum having begun, the conclusion of the act is left to nature. It is necessary to dilate the cervix rapidly before employing the curette, in order to admit of its ready introduction, and to facilitate the removal of the uterine contents. It is needless to add that the strictest antiseptic precautions should be observed.

THE HOT SPRINGS HOSPITAL.

SEVERAL years ago the late Senator Logan visited Hot Springs, Arkansas, and obtained there so much relief from rheumatic troubles, with which he was afflicted, that he determined to make the benefits of the place available for the army and navy, and to that end obtained an appropriation for the construction of a hospital at Hot Springs for the use of the officers and men of those services. The sketch plans for this hospital were prepared by Dr. Billings, of the Army, and these, after approval by the Secretary of War, were elaborated, and detailed drawings and specifications prepared by a Washington architect, Mr. Smithmeyer. The buildings are now completed, Dr. R. S. Vickery, of the Army, has been assigned as surgeon in charge, and a circular from the War Department announces that the hospital will be opened for the reception of patients January 17, 1887. The circular says:

"Relief may reasonably be expected from the use of the Hot Springs water in the following classes of diseases, viz., gout and rheumatism in their various forms, after the acute or inflammatory stage has passed; neuralgia, peripheral or central, especially when depending upon gout, rheumatism, specific infection, or metallic poisoning; paralysis, if not recent, progressive, or organic; locomotor ataxia, or tabes, if not in advanced stages, and especially if traceable to specific infection; Bright's disease of the kidneys, only in the early stages; diseases of the bladder and urinary organs; functional diseases of the liver; dyspepsia; chronic diarrhœa and catarrhal diseases generally; chronic skin diseases, especially of the squamous or scaly forms; chronic conditions, resulting immediately from specific infection, either syphilitic or malarial; chronic alcoholism.

"In general terms, it may be stated that the Hot Springs water acts by stimulating all secretions and organic functions, increasing appetite, promoting digestion and assimilation; favoring tissue change and excretion of waste products, relieving internal congestions, and stimulating the blood-making function.

"In the following classes of diseases the use of the Hot Springs water is contraindicated: All acute, inflammatory diseases; tuberculosis; organic diseases of the heart and brain; aneurism; cancer; and all diseases in which stimulation of the circulation is to be avoided."

The hospital will accommodate about twenty officers and sixty-four enlisted men. Authority for admission to it is to be obtained from the Adjutant-General of the Army or from the Surgeon-General of the Navy.

In Europe it is very common to provide special hospital accommodation at certain mineral or thermal springs for the benefit of the army, but this is the first time it has been tried in this country, and the results will be looked for with interest. It should be possible from the records of this hospital to obtain much more definite information than we at present possess as to the real therapeutic efficacy of the Hot Springs waters.

MYXŒDEMA.

ORD, to whom the profession is indebted for the best description of this disease, holds that sporadic cretinism is only myxœdema beginning in early life, before development is complete; and since Kocher's observations the opinion has been widely held that myxœdema, cretinism, and cachexia strumapriva are phases of the same essential condition and due to the same cause, namely, to abolition of the function of the thyroid gland. We have already referred to Horsley's experiments on monkeys, in which removal of the thyroid gland, carefully performed, without injury to the nerves, was followed by the symptoms typical of myxœdema; and also to the interesting paper by Reverdin on the identity of spontaneous and operative myxœdema. In addition to what is there stated we would call attention to the fact that, in the *Medical Record* of January 24, 1885, Kinnier gave an account of a case of spontaneous myxœdema, in a woman forty-five years old, with characteristic symptoms, and emphasized the identity of the symptoms with those of the so-called cachexia strumapriva. Wadsworth has also described an interesting case in the *Boston Medical and Surgical Journal* of January 1, 1885. Further, Miller has reported, in the *British Medical Journal* of February 28, 1885, the case of a woman, thirty-eight years old, who developed myxœdema after labor accompanied by profuse hemorrhage; while Suckling, in the *Lancet* of May 16, 1885, gives an account of a case of myxœdema in a woman seventy-six years old.

All these cases go to show that there is a spontaneous myxœdema which cannot be distinguished from that which follows removal of the thyroid gland. They do not, of course, invalidate the opinion that the latter is dependent upon the operation. There is entirely too much evidence now accumulated to permit any doubt that the removal of the thyroid gland may be followed by myxœdema in patients who had not manifested any tendency to it, and it cannot be denied, in the face of Horsley's experiments on monkeys, that it may follow the operation in cases in which there is no reason whatever to suspect a latent tendency to it. The

similarity of the manifestations of surgical and spontaneous myxœdema does not establish the fact that they are identical diseases, so far as their essential cause is concerned. Nevertheless, it is curious to observe that most of the cases of spontaneous myxœdema occur in persons who have passed the period at which goitre usually develops, and this fact furnishes some support to the theory of Ord that it is but a later manifestation of a tendency which, under circumstances favorable to its early development, shows itself in enlargement of the thyroid gland. It may yet be shown that goitre is Nature's safety-valve, which, being removed, the pathological process is only diverted and manifests itself in a different set of tissues. The effect of removal of a healthy thyroid gland may even similarly let loose upon the adjacent tissues forces which were innocent so long as they were undisturbed. If this view seem reasonable, we think that there may be, hereafter, more harmony between those who hold the opinions of Ord, and those who consider spontaneous and surgical myxœdema to be distinct disorders.

BRAIN INJURY IN FORCEPS DELIVERY

At a recent meeting of the Edinburgh Medico-Chirurgical Society, Byrom Bramwell showed a boy suffering with left hemiplegia, which he attributed to an injury received at birth. The delivery of the patient's mother was tedious, and had been finally effected with the forceps. Since infancy the child had been subject to epileptiform seizures, but at the time of observation there was no mark of injury of the cranium. The surgical aspect of this case involved the question of operative interference, suggested by the fact that the patient could localize a painful point over the motor area of the left arm. The judgment of the Society was adverse to it, and we do not see how it could have been different.

This case, however, is not cited so much on account of its surgical aspects as on account of its bearing upon the question of the effect upon an infant of the compression of the head by the forceps. That decided compression of the child's head often takes place in forceps delivery, in spite of the greatest care on the part of the accoucheur, and notwithstanding the use of the most suitable form of forceps, cannot be doubted, and it would be interesting to have some collection of the proportion of cases in which subsequent manifestation of brain disturbance could be reasonably attributed to the accidents of such delivery.

One of the ablest neurologists of this city entertains the opinion that very many cases of impaired brain function are due to compression at the time of birth; and his opinion seems reasonable enough. The case related by Bramwell is one in point, and others might be cited. Although it is not perfectly clear, it may be, however, that those who think that the remote dangers to the child in forceps delivery are much greater than is generally supposed, may speak more from a general impression than from a careful study of the subject. Still, their views are so plausible *à priori*, that it is desirable that enough evidence be collected to settle the question definitely for the benefit of the many accoucheurs who apply the forceps frequently.

At the annual meeting of the College of Physicians of Philadelphia held January 5, 1887, the following officers were elected: President, S. Weir Mitchell, M.D.; Vice-President, John H. Packard, M.D.; Censors, Drs. Lewis Rodman, William Goodell, Alfred Stillé, and Samuel Lewis; Secretary, Isaac Norris, Jr., M.D.; Treasurer, Charles Stewart Wurts, M.D.; Honorary Librarian, James H. Hutchinson, M.D.; Recorder, J. Ewing Mears, M.D.

At the annual meeting of the Philadelphia County Medical Society, held on January 5, 1887, the following officers were elected: President, Dr. J. Solis Cohen; Vice-Presidents, Drs. W. W. Keen and E. T. Bruen; Secretary, S. Solis Cohen; Treasurer, L. K. Baldwin; Censors, Drs. Joseph Hearn and De Forest Willard.

Dr. John Scott, of San Francisco, an active and able gynæcologist, died on December 24, 1886. He had been largely instrumental in founding the California State Woman's Hospital, and was a member of the State Society, the San Francisco Obstetrical Society, and, at the time of his death, Vice-President of the American Gynæcological Society.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

[illegible] *Meeting, January 5, 1887.*

The President, A. Jacobi, M.D., in the Chair.

ELECTION OF OFFICERS.

The annual election of officers resulted as follows:

President.—A. Jacobi, M.D.

Vice-President.—Wm. H. Draper, M.D.

Treasurer.—Wm. F. Cushman, M.D.

[illegible] Lewis Balcock, M.D.

Member of the Committee on Admissions.—H. E. Crampton, M.D.

Member of the Committee on Publication.—[illegible] T. P. Kinnicutt, M.D.

[illegible] Dr. J. Lewis Bryant, read a paper on

THE ANTISEPTIC TREATMENT OF SUMMER DIARRHŒA.

The term summer diarrhœa, he said, he used for the reason that it expressed an affection with which all are familiar, without raising any questions in regard

to the pathology of the conditions present. While this paper was specially devoted to the medicinal treatment, the author laid stress upon the point that other methods of treatment than the use of drugs were not ignored by him. It is of prime importance that suitable food and the best hygienic surroundings should be secured for the patient. Unfortunately it is often impossible to secure satisfactory sanitary conditions for the children of the poor in large cities; but with suitable care and the use of appropriate remedies, much could be accomplished.

These cases of summer diarrhœa, with the exception of instances of pure cholera infantum, Dr. Holt believed, are all of dyspeptic character, and are primarily due to fermentation or putrefaction in the intestines. Among the factors entering into the causation of the trouble, he mentioned heat, improper feeding, and bad hygienic surroundings. The affection is evidently not due to heat alone, or else we should find that the greatest mortality was among infants under six months of age, which is not the case. During the first six months a much larger proportion of children are wet-nursed than later on, and it is after this age that the summer diarrhœa is the most fatal.

In speaking of the influence of heat, he spoke of its effects upon the food as well as upon the child, and referred to an instance in which, at the New York Infant Asylum, no less than twenty-three children became affected with diarrhœa in a single day from the use of tainted milk. In tenement-houses, all the conditions are exceedingly favorable for the contamination of milk, and it is only a wonder that more children do not suffer from this cause than is actually the case. In this connection he spoke of the development of poisonous ptomaines from food, and alluded particularly to the investigations of Professor Vaughan, of the Michigan State Board of Health, in regard to the principle which he has designated as "tryrotoxicon." Brunton's researches he also thought had furnished the solution of many hitherto insoluble problems. Cerebral symptoms have been generally supposed to be due to the sudden stoppage of the diarrhœa. Huchard has shown, however, that poisonous ptomaines are evolved from human feces in health; and this is the case to a much larger extent in disease.

In summer diarrhœa, Dr. Holt went on to say, the inflammatory changes are usually in the large intestines, and colitis is secondary and consequent. A specific microbe, as the cause of the disease, has not as yet been demonstrated; but quantities of bacteria, of various kinds, are always found to be present. The indications for treatment are as follows:

1. Clear out the bowels.
2. Stop decomposition.
3. Restore healthy action in the bowels.
4. Treat the consequences of the intestinal disease.

In the first place, it is necessary to clean out the bowels, for the same reason that the surgeon thoroughly cleanses a wound before applying his antiseptics. In all cases Dr. Holt begins his treatment with a cathartic, in order to remove the altered secretions, and if the stomach is not very irritable, there is nothing which, in his opinion, is to be compared to castor oil for this purpose. If the stomach is irritable, he is in the habit of using large injections of water by means of a fountain syringe. He has found by experiment that it takes about a pint of water to reach the ilio-cæcal valve, and at least this quantity should be used. In many cases the castor oil is all the medicine that is required, if proper food and general care are employed afterward, and the usefulness of this remedy is perhaps better understood by the laity than by most of the profession. In cases, however, in which the passages, consisting of pure serum, are odorless and alkaline in reaction, no preliminary cathartic is required.

In order to stop decomposition and restore healthy action in the bowels, he said he had found salicylate of sodium the most efficient agent. If there is much vomiting, it is better to withhold food altogether for from ten to twenty-four hours; employing carbonic acid water, or thin barley water, for allaying thirst. In children under two years of age, no milk whatever should be allowed; but in case milk is employed, peptonized milk is much less likely to do harm than either condensed or ordinary cow's milk. He has known many relapses to be brought on by the use of milk.

The treatment of the consequential lesions was the fourth point considered. When a condition of ulceration has been reached, he believes the use of astringents to be absolutely valueless. Three things are required for a cure: (1) Appropriate dietetic treatment; (2) the continuance of the antiseptic; and (3) the washing out of the whole large intestine every day with pure water, or with a weak antiseptic or astringent solution. The chemical agents which he prefers for these injections are benzoate of sodium and nitrate of silver. It is a fact, he said, that all drugs which have formerly proved useful in the treatment of summer diarrhœa, with the exception of opium (in regard to which there has been much discussion), are of a more or less antiseptic nature.

Dr. Holt then proceeded to give a *résumé* of the history of the use of antiseptic remedies proper in this affection, from the time when Mays first employed creasote in 1846. As long ago as 1853, Matthison had reported much success from the use of salicine, and in 1858 S. W. Smith published in the *British Medical Journal* his successful experience with willow charcoal. In 1879 Kilner used salicylate of bismuth and calcium at St. Thomas's Hospital, London; and in 1880 Hutchins, of Brooklyn, reported good results from the use of salicylate of calcium alone. Segue, of Brooklyn, also meet with much success in the treatment of the diarrhœa of phthisis with the salicylates. In 1886 Braithwaite recommended, in the *British Medical Journal*, the use of salicylate of iron, which he had found very efficient. Naphthalin has been highly lauded by Fallenberg and other writers, and bichloride of mercury is recommended in Ringer's *Therapeutics*. Rosenberg, Millard, and Marten, have reported good results with the latter remedy; and Schultz has treated seven cases of dysentery with it, with but one fatal result.

Even the most recent text-books on diseases of children, Dr. Holt went on to say, advocate practically the same treatment for summer diarrhœa that was in vogue fifty years ago. In order to find out what is the present practice in New York institutions, he wrote to the physicians of fourteen of them, including the Nursery and Child's Hospital, the Foundling Asylum,

St. Mary's Hospital for Children, the Demilt Dispensary, and a number of other prominent hospitals and dispensaries, in which upward of 40,000 children are treated annually—25,000 for diarrhœal diseases. He found, among other facts, that opium is used in nearly all, and bismuth in all. Castor-oil, as a preliminary medication, is used in six, and castor-oil emulsion, with equal parts of the oil and paregoric, in three. Chalk-mixture, in combination with paregoric and an astringent, is used in several; calomel in three; ipecac in three; pepsin in one; iodoform in one; morphia and atropia hypodermatically in one; and astringent injections in three.

Dr. Holt said that in his own experience he had found that with the use of opium, bismuth, and astringents, 50 per cent. of cases were cured, 27 per cent. were improved, 17 per cent. were not improved, 7 per cent. died. Abstinence from milk was not so strongly insisted on in his earlier cases as in his later ones. A year ago last summer he first commenced the use of salicylate of sodium. In about two-thirds of the cases in which he used it he gave castor-oil as a preliminary to the treatment. In a few cases where there was great irritability he employed Dover's powder simply for the purpose of controlling this. Out of 81 cases treated with the salicylate of soda, 60 were cured, 14 improved, 6 not improved, and 1 died. The results of all his cases were as follows: Cured, 84 per cent.; improved, 7 per cent.; not improved, 7 per cent.; died, 1 per cent. The unimproved cases, he said, illustrated the difficulty of keeping up a proper course of treatment among the children of the poor.

Of 44 cases in which he had employed naphthalin, 67 per cent. were cured, 15 per cent. were improved, 13 per cent. were not improved, and 1 per cent. died. In 27 cases treated with resorcin, 22 per cent. remained unimproved; and it soon became evident to him that this agent was not nearly so efficient as either salicylate of sodium or naphthalin. He had also used bichloride of mercury in 28 cases, but had not found it as successful as the remedies named. The comparative results of treatment by these different remedies were, then, as follows:

Cured by	opium, bismuth, etc. .	50 per cent.
"	" salicylate of sodium .	84 "
"	" naphthalin . . .	67 "
"	" resorcin . . .	55 "

Dr. Holt then related a case seen in consultation, which illustrated the value of salicylate of sodium. The child was seventeen months old, and was first seen by him on the fifth day of the disease, when it was in an apparently hopeless condition; the ordinary treatment by bismuth and opium having entirely failed to arrest its progress. The rapid, weak pulse, elevated temperature, and other unfavorable symptoms which were present he attributed to the toxic effect of the decomposition which was taking place in the intestinal canal. He suggested the employment of castor oil, to be followed by the salicylate of sodium. The physician in attendance strongly objected to the cathartic dose, on the ground that the child was not strong enough to stand its depletory effect. He was finally persuaded to try it, however, and the patient rapidly improved under the antiseptic treatment by which it was followed.

Dr. Holt gives the salicylate of sodium in doses of from one to three grains, every two hours, and in the form of an aqueous solution, which can be taken with the food or drink. Instead of producing vomiting, he has found that it often allays irritability of the stomach. Naphthalin can be given in doses of from half a grain to five grains, and resorcin in doses of from half a grain to two grains. Bichloride of mercury is apt to disagree with the stomach, and he has known doses of $\frac{1}{150}$th to $\frac{1}{60}$th of a grain produce vomiting.

While summer diarrhœa is not to be regarded as depending on a single uniform agent, the immediate cause of diarrhœa must be looked for in the putrefactive changes taking place in the food (which, indeed, often begin outside the body before it is eaten); diarrhœal discharges, at the outset at least, should be regarded as salutary. Dr. Holt mentioned that he does not undervalue the efficiency of opium in other forms of diarrhœa. In conclusion, he said that the use of evacuants constitute an essential part of the antiseptic treatment of the disease under consideration, and that, as the result of his experience, he gave the preference to salicylate of sodium after a cathartic had been employed. The antiseptic treatment is especially valuable, because it removes the cause of the trouble in the intestinal canal, and does not simply combat its effects.

Dr. Wilcox related his experience with naphthalin in the treatment of diarrhœa, stating that he had employed it in thirty-two cases, nearly all of which, however, were in adults. In his hands it had proved so efficient that he had come to regard it as of the same value in diarrhœa as mercury, and iodide of potassium in syphilis, or quinine in malarial trouble. In order to secure its full effect the patient should take at least 60 grains a day, and in some cases 120 grains a day are required. He gave it chiefly in starch capsules, with oil of bergamot to conceal its odor. Occasionally he had found that the urine became smoky under its use, but no albumen or casts could be detected in it. He had employed it with excellent effect in eighteen cases of chronic diarrhœa, and some cases of chronic dysentery. In one case of twenty-five years' standing, in a man sixty-one years of age, a cure was effected by the use of 90 grains a day.

In two cases he had employed it successfully in the diarrhœa of typhoid fever. The patients were in the third week of the disease, and took from sixty to ninety grains a day; which reduced the stools to two in the twenty-four hours, and rendered them perfectly odorless. Naphthalin also had an antipyretic effect in these cases, and he regarded it as quite as safe as any of the antipyretics now so commonly employed, such as antipyrin, thallin, and antifebrin. He had also tried resorcin to some extent, but with very different results.

Dr. Andrew H. Smith remarked that it had been his idea for some time that the cause of summer diarrhœa could be best treated by the aid of antiseptics. The essential oils which are in common use in domestic practice are really antiseptics, and the same is true of the pennyroyal, spearmint, and peppermint teas so often resorted to in the country.

Dr. John C. Peters said that he believed he was among the first to designate summer diarrhœa as a filth disease. Bacteria will live in opium and in a ten grain

solution of calomel. He agreed with Dr. Smith in regard to the antiseptic value of the mints.

DR. VAN SANTVOORD said that Dr. Holt was no doubt correct in considering the disease primarily dyspeptic in character. In the Infants' Asylum, on Randall's Island, he had been in the habit of using opium where there had been frequent and watery passages, and he often gave it hypodermatically, employing from five to ten minims of the officinal solution of sulphate of morphia, with from $\frac{1}{300}$th to $\frac{1}{200}$th grain of atropia. Bismuth he regarded as of service, not simply from its mechanical effect, but because it is a true antiseptic, and he gave it in suitable doses after each feeding. The inflammatory changes in summer diarrhœa are largely located in the large intestine, and he thought that large astringent injections should be used to flush out the colon. He combined an alkali with the astringent in these injections in order to be able to get at the mucous membrane by removing the mucus from it. Nothnagel has shown that strong saline solutions excite retroperistalsis in the intestines, and he thought that these might perhaps be used with good effect.

The PRESIDENT heartily agreed with what Dr. Holt had taught in his paper, and particularly as to the antiseptic character of remedies long in use. As regards pepsin, which he never regarded as simply an inert mechanical substance, he had published an article twelve years ago, in the *American Journal of Obstetrics*, in which he distinctly claimed that it was an antifermentative; and such was still his conviction. He also agreed with Dr. Holt, as to the importance of appropriate dietetic treatment. If there is one special danger in summer diarrhœa it comes from the use of milk, and for twenty-five years he had taught that the disease could not be cured without the omission of milk. It is often necessary to withdraw it for a number of days; but there are plenty of things that can be resorted to which take its place. As a rule, he substitutes for it the white of egg, raw, mixed with barley water, or other farinaceous drink. Forty years ago Meiser, of St. Petersburg, advised the use of raw meat; but although this in some respects is an excellent form of nourishment, it should be avoided if possible, on account of the danger of introducing into the system the tænia canellata, a much more formidable variety of tapeworm than the ordinary tænia solium, because of the difficulty in removing it.

DR. GEORGE H. PEABODY said that he had come to look upon naphthalin as a very valuable addition to our therapeutic resources in a number of intestinal complaints. For some time past he has been using it in all the earlier cases of typhoid fever which came under his care at the New York Hospital. It is reasonable, he thought, to look for relief in a remedy which acts directly on the local lesions, and several cases have already occurred in his practice in which the disease was apparently aborted by this remedy. He referred particularly to a case which came under treatment on the second day of the disease. By the thirteenth day the fever was gone and convalescence had commenced; yet the patient had had the usual prodromal symptoms, and the characteristic eruption and enlargement of the spleen had afterward been well marked.

Dr. Peabody also mentioned a case of chronic diarrhœa of twenty-one years' standing, in which the patient never had less than seven movements a day. He had been under treatment for a broken leg in the surgical wards of the hospital; but though while there the usual astringent remedies were employed, the diarrhœa still continued unchecked. On his transferral to the medical wards he was placed on the use of naphthalin, and in ten days the case was cured; the passages by that time having become normal in quantity, color, consistence, and odor. He also mentioned another case in which the patient, who had had repeated attacks of chagres fever in Panama, suffered from chronic diarrhœa for four years. He also was completely cured by naphthalin, without the aid of astringents. All his cases of typhoid fever, Dr. Peabody said in conclusion, are given a preliminary full dose of calomel.

DR. WESLEY M. CARPENTER referred to the remedies which he had seen used with good effect in country practice. The first was hard cider, which was used with much benefit by veterans of the late war suffering from chronic diarrhœa. The second was salicin, which he had seen successfully employed in a large number of cases of dysentery and diarrhœa, including tubercular diarrhœa. Both these agents belong to the group of antiseptics.

DR. ARCHER H. SMITH asked if it was not true that the salts of salicylic acid are efficient only in the presence of acids.

DR. HOLT replied that the acids in the stomach and intestines would cover the case. Dr. Cauldwell, whom he had expected would be present this evening, had used salicylate of sodium with much success in twenty cases of the diarrhœa of phthisis.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 8, 1886.

TUMOR OF THYROID REMOVED BY SOCIN'S METHOD.

DR. WEIR showed a tumor recently taken out of the substance of the thyroid gland after the method advocated by Socin, of Basle. This surgeon, he stated, in order to avoid the necessity of extirpation of the thyroid, with its consequent risk of myxœdema, had called attention to the fact that in most cases the new growth of thyroid tissue or of neoplastic elements could be readily separated from the normal gland tissues. To do this, it is only necessary to cut through the overlying stratum of healthy thyroid until the capsule of the tumor is reached when enucleation can easily be accomplished. The divided gland tissue may give rise to considerable venous oozing, but this is easily controlled. Socin's experience embraces now over fifty cases without any cachexia strumapriva following. In the case presented by Dr. Weir the tumor was found in the person of a dwarf of twenty-one, who was defective mentally, and had an appearance suggestive of commencing myxœdema, and in whose neck, on the left side, was an enlarged irregular thyroid gland which had existed since infancy. On the right side there was no general enlargement of the gland to be seen or felt, but nearly on a level with the larynx was a roundish movable tumor the size of a hen's egg, which had appeared within the past eighteen months, and which caused considerable pain on that side of the head. It was also increasing in

size. It moved with the trachea in swallowing. It was explained to the mother, who was anxious to have all the growth removed, perhaps for a commercial reason, that this ought not to be attempted, and that only the swelling, now increasing in dimension, could be interfered with. An incision was made vertically over it, the thyroid gland reached, and its substance, of a deep red color, cut through to the depth of more than a quarter of an inch until the tumor was exposed freely, when with the end of the scalpel and with the finger-nail the enucleation of an hour-glass-shaped growth two inches long and three-quarters of an inch wide was promptly accomplished. The venous oozing from the substance of the thyroid gland was easily checked by clamps and ligatures, and the cut gland edges sewed together except at the lower end, where a drainage tube was inserted, and then the skin cut was sutured in a similar manner. Secondary union occurred.

The following is the report of the pathologist, Dr. Peabody:

The main tumor is spheroidal in shape and in great part surrounded by delicate fibrous capsule. It is about three-quarters of an inch in diameter. Connected with it is a smaller one of same color, consistency, and general character. It is very friable, not easily cut for microscopic examination. Sections show it to be divided into lobes which present the appearance of compound racemose gland, with tubes and ducts lined by cylindrical epithelium. The general epithelium of the gland is shapeless. Diagnosis, adenoma.

SARCOMATOUS FLOATING TUMOR OF THE KNEE-JOINT.

DR. WEIR presented a sarcomatous pedunculated tumor which he had removed, October 23, 1886, from the left knee-joint of an Italian aged forty-two years, who had had disability in that articulation for several months. At first beginning as an ordinary synovitis, to this were supplemented soon sundry painful "catchings" of the joint, with aggravation each time of the difficulty in walking. On the inner aspect of the knee could be felt a movable, rather hard body the size of the end of the forefinger, whose excursions were limited to that side of the joint in an area corresponding nearly to the upper limit of the patella. On making an incision, under carbolic spray, down to the mass previously fixed by a tenaculum, it was found to be, instead of cartilage, a reddish-yellow tumor about an inch long, attached by a slender pedicle which, after being tied with catgut was severed, and the growth removed. The wound was not sutured but dressed antiseptically and the limb secured in a posterior splint. No reaction followed, and at the end of ten days the dressings were taken away, and the patient allowed to move his limb cautiously about the bed. A week later he began to walk. On November 22d, when the patient was fit to be discharged from the hospital, without any intimation he leaped from the window of his ward and fell a distance of four stories and killed himself. Among his other injuries a compound fracture of the left tibia occurred. The tisues of the joint were carefully examined microscopically to see if any changes similar to those observed in the tumor removed by the operator existed, but none were found. The reason for this was that the movable body was reported by the pathologist to be a fibrosarcoma. His statement in detail is as follows:

Pathologist's Report.—The tumor presented for examination is flattened, caudate, and measures $2 \times 1 \times \frac{1}{2}$ centimetres. It has been incised over its whole length. It weighs five grammes. Microscopic examination reveals it to consist of fibrous stroma with varying amounts of small spindle cells. In some places these lie close together; in others they are few and scattered. It also contains numerous arteries with normal walls, and there is a great deal of blood-pigment scattered generally through the tissue.

As this is apparently the first case in which a post-mortem examination has been held, it is interesting as confirming the statement made in a recent article published by Dr. Weir on this subject, that clinically it is sufficient to remove the offending mass. His first case, operated on in 1884, is still free from recurrence, and lends additional support to this view.

LAPAROTOMY FOR SUPPURATIVE PERITONITIS FROM ACUTE PERFORATION OF APPENDIX VERMIFORMIS.

DR. WEIR exhibited the cæcum and stump of an appendix vermiformis fistule closed by several silk sutures, which had been obtained from the post-mortem of a laparotomy case operated on by him December 6th, and the details of which, taken from the hospital note-book, were as follows:

Edward V., aged twenty, single, Canadian, was admitted to the New York Hospital, Medical Division, Dr. Vought, House Physician, December 6, 1886, with the history that he had been well till seven days ago when, on account of headache, he took two cathartic pills without relief. At this time he was exposed a good deal to cold and wet. He kept on taking cathartic pills and had following this an attack of diarrhœa. Four days ago he began to have pain in the abdomen which grew more more and severe, especially in the right iliac region. He has also had some cough, and vomited eight or ten times during the past week. Last night he had a severe and this morning more severe and general pain in abdomen.

Examination.—Abdomen swollen and very tender on slight pressure. Breathing entirely thoracic. Patient lies in dorsal decubitus; knees not constantly drawn up. In right iliac region there is a feeling of resistance and over this a slight dulness. Over the rest of the abdomen the resonance is tympanitic. The abdominal muscles are rigid; splenic area large. A needle inserted into right iliac fossa the depth of one and one-half inches draws sero-purulent fluid. Posteriorly, on left side and low down, inspiration is rough and a few rough râles are heard over chest. Temperature 102.8°; pulse 135; respiration 32 at 4 P. M.

Transferred to surgical division, Dr. Hughes, House Surgeon, at 9 P. M. Operation by Dr. Weir. On examination after etherization no marked dulness or swelling was found in the iliac fossa, but an aspirating needle inserted near previous puncture in right iliac region withdrew pus with the needle *in situ;* for a guide an incision two and a half inches long was made just above Poupart's ligament upward and outward and extending beyond the superior spinous process. On opening into the abscess cavity considerable watery pus flowed out. By digital examination it at first appeared as if the abscess had been limited on its inner side by the adherent coils of intestines, which could be plainly felt.

The unusual amount of discharge, however, led to a more free examination, and it was soon recognized that the general cavity of the peritoneum was involved in a suppurative peritonitis.

A median laparotomy was then decided on. An incision was made on the median line about six inches long; afterward enlarged so as to extend from symphisis to three inches above umbilicus. The parts were found very much congested. There was a large exudation of pus with free soft adhesions. The intestines were partially taken out and laid in hot towels and the right side of pelvis carefully examined. A perforating ulcer was found at root of vermiform appendix on its free surface, posteriorly throughout its whole length it had a mesenteric attachment. In order to occlude this satisfactorily the entire appendix was tied off with catgut and the stump ligated and covered in by peritoneum, by several Lembert's sutures made with fine black silk. The abdominal cavity was thoroughly douched with warm water and intestines replaced, and a duplication of iodoform gauze was inserted in the midst of the intestines, in the iliac fossa, and in the pelvis (Mikulicz's method). A large rubber drainage tube was also introduced in iliac fossa through first wound, and another into the pelvis through the lower end of the median incision. The median incision was sewed together with strong silk. Bichloride compresses and cotton dressings were applied, all secured by a binder. No intestinal concretion was detected in the appendix or in the peritoneal cavity.

The patient's condition grew rapidly worse during operation; administered fld. ext. digitalis ♏ iv, and whiskey ℥ij hypodermatically, and per rectum, atropine gr. one-forty-eighth, with firm bandaging of the extremities. At termination of final dressing his condition was encouraging, color good. Pulse 185 and moderately strong at wrist. Immediately after the operation was given a hot air bath and hot water bottles were placed around him.

12 midnight, temperature 101.2°, pulse 180, respiration 34; an enema of milk ℥ij, whiskey ℥j. Ordered tr. strophantus ♏iij and brandy ℥ij, every three hours by mouth, and whiskey by mouth and by rectum.

Dec. 7. 3 A. M. Administered hypodermatic of Majendie ♏ iv. at 11 P. M. to quiet restlessness. This was repeated at 1.50 A. M.

3 A. M. Temperature 102.8°, pulse 80, respiration 24.

3.30 A. M. Died.

The post-mortem showed that the peritoneum was intensely congested and covered with recent lymph. There was about one drachm of pus in the pelvis. The spleen was a trifle enlarged. The omentum was rolled up toward the transverse colon. The mesenteric glands were large. The stomach was normal. The common bile duct was pervious. Mucous surface of the duodenum was normal. Some of Peyer's patches were pigmented. The mucous surface of small intestine otherwise normal.

The vermiform appendix had been removed and its attachment to the cæcum apparently closed by a ligature. The surgically removed vermiform appendix was markedly thickened by a swelling of all its coats. Its interior was lined by a thick ragged false membrane and there was a perforation near its attached end. The right lung, on its anterior aspect, showed evidence of recent pleuro-pneumonia.

Dr. Weir remarked that there were two points connected with this case of particular interest. One was the difficulty of determining without exploratory iliac incision and sometimes even after this was done, whether or not the typhlitic abscess was yet a local affair. Peritoneal symptoms were not unfrequently seen with perityphlitic inflammations, especially with that variety which resulted in limited peritoneal abscess. It is possible to get pus by an exploring needle from a collection not recognizable to palpation and it is also possible, and it nearly was accomplished in this case, to open into the general peritoneal cavity and yet be deceived into thinking it a localized abscess. The absence of tumor and profuseness of thin sero-pus led to a renewed and thorough examination which had, until then, been refrained from lest limiting protective adhesions should be broken down. The second point was the treatment of the perforated appendix. Should the sloughy opening be trimmed off and its edges inverted and closed as in an intestinal perforation and the appendix preserved, or should it be boldly removed as in his case? The closeness of the perforation to the cæcum interfered with his desire to cut away the sloughy edges left even after the excision of the appendix, but where practicable this, he thought, should be done before the Lembert sutures were applied. He, however, knew that simple ligation without peritoneal inversion had frequently sufficed where the appendix had been removed in this and other difficulties. He favored the usual extirpation of the appendix as not adding to the risk and as preventing future trouble.

Dr. Sands believed that in the vast majority of cases of what we term peritonitis, which terminates in abscess, the disease arises externally to the peritoneal cavity. He had operated for perityphlitis a great many times, but had never yet found a circumscribed abscess bounded simply by coils of adherent intestine. He was aware that such is a common view, but he believed it to be inaccurate. He also had observed that when perforation of the appendix occurred into the serous cavity the result was invariably fatal. A short time ago a case came under his observation in which the symptoms of circumscribed tumor were wanting, but in which there were present marked pain and tenderness in the cæcal region. In that case, upon incision through the abdominal wall over the seat of tenderness, a small amount of pus escaped; and on putting the finger into the opening the feeling of intestine was imparted. The patient died a few hours after the operation, and no examination was made post-mortem.

Dr. Briddon remarked that he had made autopsies in three cases where death occurred in from twenty-four to thirty-six hours, from perforation of the appendix; there were no limiting adhesions but general profuse peritonitis; no formation of an abscess at all, as he did not think there was time.

Dr. Sands said, in reply to Dr. Weir's remarks, that he had carefully explored many cases of perityphlitic abscess, but had never found a boundary wall of intestine; he had felt the colon and the cæcum at the bottom of the wound, but had only been able to recognize bare intestinal coils in a very few cases in which there was no circumscribed abscess, and in which he could determine the presence of pus within the peritoneal cavity.

In one instance he was called in consultation to see a

gentleman who was said to have had symptoms of perityphlitis. But, at the time of his visit the tumor in the cæcal region had subsided and the patient was almost comatose. The cause of the coma proved to be meningitis, and at a post-mortem the subsidence of the tumor was found to be due to the pus having travelled within the sheath of the psoas muscle, the intestinal walls forming no part of the boundary of the abscess. As regards Mr. Treeve's investigations, he would not dispute their accuracy, but he could not advise very early operative procedures, as he had seen so many of these cases terminate favorably without incision; a few tumors had ruptured spontaneously, but the majority had subsided without evidence of rupture. He believed that very few cases would be injured by being allowed to remain for a week or ten days, according to the local symptoms; the speaker, however, considered that to operate always within two or three days from the onset of the disease would be much like performing laparotomy for every case of pain in the abdomen.

THE PRESIDENT asked Dr. Sands if he did not think the use of the exploring needle of advantage in these cases of perityphlitis, before the end of a week or ten days, in order to enable the surgeon to decide as to the date of operation.

DR. SANDS replied that, so far as his experience went, he had always found it safe to wait. He deprecated early operations, first, because they might be unnecessary, and secondly, because they might be unsafe. Regarding the first point, he had seen a large number of cases in which the inflammatory swelling had subsided without any surgical operation, and the patients had got well. The danger of spontaneous opening of the abscess at an early period into the peritoneum he believed to be exaggerated, and to be unsupported by clinical facts. He could recall but a single instance in which such a rupture had occurred as early as the seventh day of the disease.

Concerning the second point, namely, the risk attending early operation, he believed it to depend on the liability of the entrance of the fetid contents of the abscess into the peritoneal sac. He thought that perhaps he had not made himself clearly understood when he had contended that circumscribed perityphlitic abscesses are usually external to the peritoneum. He did not mean to deny the anatomical relations of the cæcum, which he thought are generally understood. But he failed to see why the almost complete investment of the cæcum by the peritoneum, or the presence of a mesentery attached to the appendix vermiformis, should determine the entrance of fecal matters escaping from a perforated appendix into the peritoneal cavity. His supposition was, that in cases of circumscribed abscess due to such perforation, this was preceded by adhesion of the serous membrane covering the appendix to that lining the iliac fossæ, and that thereby the latter was lifted by the pus and fecal matter and the invasion of the peritoneal sac prevented. But adhesions would not usually be limited to the perforated appendix; it would often involve the peritoneum covering the cæcum, the abscess, and the back of the anterior abdominal wall. Such adhesions, however, would be absent at an early period, and hence one danger connected with early incision. He remembered several cases in which the presence of pus had been demonstrated by the use of an aspirating needle, and in which an incision made carefully along the latter held *in situ*, opened the peritoneal sac, adhesions not having yet taken place. After closing the opening made in the serous sac, adhesion ultimately occurred, and the abscess evacuated its contents externally with safety, and without further surgical operation.

It is fair to presume that the simultaneous opening of the peritoneal sac and the cavity of the abscess might have been followed by a fatal result. Dr. Sands would not dispute the desirableness of an early evacuation of the contents of a perityphlitic abscess, but he thought that the danger attending such operations should be duly weighed. Another reason for delay is that even when the peritoneum covering the abscess does not become adherent to that lining the back of the anterior abdominal wall, the line of reflection may be pushed upward by the growing swelling, so as to be above that generally selected for incision.

DR. BRIDDON remarked that a patient in the service of Dr. Andrew H. Smith was referred to him, in whose case there was a swelling, the most prominent portion of which appeared to be about three inches above Poupart's ligament, with a zone of less resistance immediately above the ligament. An aspirating needle was introduced one inch above the ligament and gave exit to pus; it was left in position and the usual incision was made. When the transversalis fascia was reached it was found that the peritoneum had not been pushed up by the abscess and that the needle consequently had passed through two of its layers. It was displaced upward by the fingers until the cavity of the abscess was opened without further implication of the peritoneum than that caused by the needle. The patient made a prompt recovery.

THE PRESIDENT asked, if, given a case where there was no appreciable tumor, symptoms should lead to the use of the needle and pus be detected, would there be greater danger of opening the peritoneum at that time than in operating for ligation of the external iliac artery, the incision being made close to Poupart's ligament?

DR. SANDS thought it would be possible but considered that it might be more difficult in consequence of morbid alterations due to inflammation.

DR. BRIDDON said that he had regretted operating early in one case which was under the care of the late Dr. Wm. C. Hunter. The swelling was situate deep in the iliac fossa, and aspiration gave exit to pus. The needle was left *in situ*, and after division of the muscular and aponeurotic coverings by the scalpel, further separation was made by the fingers until a cavity was reached at a very considerable depth from the surface. It contained only a small amount of pus. It was drained and dressed in the usual way, and everything went well for forty-eight hours, when he developed an acute and rapidly fatal peritonitis.

DR. WEIR was unwilling to let the remarks of Dr. Sands pass unchallenged. He could recall three instances that had occurred tolerably recently in which, after the abscess had been opened, he could feel with his finger toward the median line several coils of small intestine which, glued together, made up the inner wall of the abscess. Moreover, the extensive researches of Treves utterly disprove the old idea of the cæcum and appendix being continuous, posteriorly or otherwise,

with the subperitoneal alveolar spaces. In fact, in a hundred dissections made by this English observer he had never yet seen the posterior surface of the cæcum uncovered by peritoneum, nor had he encountered a meso-cæcum. The reality is that in the great majority of cases the entire beginning of the large intestine is completely surrounded by peritoneum up and upon the ascending colon. Moreover, the mesentery of the appendix is derived from the ilium in nearly every instance where it existed. Hence, perforating appendicitis and the still more surely perforating cæcitis must primarily produce a peritoneal suppuration, limited or diffused, or else by the lucky occurrence of adhesion before the accomplishment of the perforation give rise thus to a subperitoneal abscess—the so-called paratyphlitis. Both varieties undoubtedly exist, but if it is admitted that the first form occurs, it is right that an evacuation of the matter should be had as soon as its presence is recognized. This can often be arrived at early by the use of an aspirator needle, or the question of time will generally decide surgical interference; this, in a consideration of over 250 cases, has been placed by Fitz at not later than the third day. With this doctrine he should agree certainly in those cases where the symptoms were marked and existed with persistent temperature elevation.

He believed that many of the cases that got well either evacuated themselves by the bowels or bladder or underwent absorption, which was not often, or were, what was more likely, cæcitis from fecal impaction and not of a suppurative character. Hence he had seen and learned to expect a ready subsidence of temperature heat after the administration of anodynes. Fitz, who had been just cited, was also firmly of the view of the intraperitoneal origin and seat of these abscesses. Bartholow, writing on the same subject, has taken a similar view. Individually he had never yet regretted operating too early in cases of right iliac inflammatory tumors.

His impression of the site of such abscesses had been formed for many years, he having been led to the investigation by once witnessing the occurrence of a rupture of a perityphlitic abscess into the general peritoneal cavity under very slight palpation of the tumor, with a rapidly fatal issue without surgical interference as the accident took place before the general use of laparotomy. Dr. Weir concluded by reiterating the fact that if a laparotomy was necessitated for an advanced general suppurative peritonitis or even in the rarer cases of acute perforation of the appendix, by lifting out the intestine filling the right iliac fossa, the entire field of ulceration was fully brought into view, and that lesions difficult to detect at a post-mortem examination could be recognized in the living subjects quite readily by changes in color and consistence which were lost in cadaveric alterations.

Stated Meeting, December 22, 1886.

DR. L. A. STIMSON IN THE CHAIR.

DR. ABBE presented the following

NOTES ON THE OPERATIVE CLOSURE OF A LARGE LARYNGEAL FISTULA.

In December, 1885, a man aged forty-five years, presented himself for treatment of an opening in the side of his larynx immediately above the vocal cords, into which the end of one thumb could be thrust. In the month of April preceding, he had tripped while rising from his cobbler's bench with a shoemaker's knife in his hand, and had so stumbled that he fell upon the point of the knife, which was thrust well into the thyroid cartilage of the left side. It was an ugly gash and bled severely. He was carefully treated in the Bridgeport hospital at once, a tracheal tube was inserted and he says was worn a month. The hole in the cartilage was just above the vocal cord attachment and laryngeal inflammation probably followed and impaired his breathing. After another month an operation was performed to close the fistula by suturing, but was ineffectual.

He then came to New York and was subjected to five more attempts at closure by his physician at home. The methods varied: Sometimes silver wire sutures were used, after paring the edges; sometimes, silk. Twice were the harelip pins and figure-of-eight suture used. But after each operation mucus and discharges burst the wound open and left him more desperate than before. The successive parings of skin and cartilage had resulted, with what ulcerations occurred between times, in the sacrifice of a considerable portion of the left lateral half of the thyroid cartilage, the entire gap being nearly three-quarters of an inch, though the opening in the cartilage proper was five-eighths of an inch in diameter. The edges of the fistula were cicatrized and induration extended half an inch from the opening. Through this great gap one could get a most extraordinary view of the vocal cords in action. The anterior ends were attached first within the lower edge of the fistula on the median side, and when at rest the cords fell flat on either side and were lost in the mucous membrane. On attempted phonation they sprung into view and vibrated at an angle of thirty degrees with the horizon—afterward falling back to nearly the horizontal position.

This movement of the cords to assume this angle with the horizon when the patient is erect I do not find noticed in such authors as I have consulted.

Attempts to speak or make audible voice when the fistula was uncovered were futile. The voice being produced in the mouth and pharynx by the utilizing of sound of vibrating cords, it was vain for him to try to phonate when all the sound escaped from the side of the larynx. All he could do was to produce a fizzing or buzzing note like the sound one might make by blowing through a single reed of a reed organ. When, however, a flat pad covered the fistula completely, he could phonate perfectly though with a slightly husky tone.

I decided that by the following not very complicated plastic operation I could close the fistula, if I did preliminary tracheotomy to prevent expulsive efforts at coughing from mucus and air passing through the sutures.

Nov. 13, 1885, assisted by Dr. Bangs, the patient was etherized and tracheotomy done at the two upper rings. When the patient breathed well through the tube the glottis was stopped through the fistula with a sponge attached to a string drawn out through the mouth. The edges of the fistula were thoroughly pared. A broad elliptical space was then included between two incisions, *a*, *b*, being somewhat wider than the fistula and extending obliquely downward on the

patient's neck. A part of the included skin below the fistula was dissected up so as to make a flap on its upper edge, which, when turned over, more than covered the hole. The cuticle was then denuded from the part of this surface not wanted to cover the hole, and the rest of the elliptical space made raw for the reception of the overturned flap. The latter was then stitched over the fistula by two rows of fine continuous catgut; one row on the edge of the orifice tacking the surface of the flap at the circle of denudation, and the second on the outer edge of the flap fastening it to the outlying tissue.

The skin on either side of the neck was then undermined and slid over the flap mentioned, so as to meet directly over its centre. A lateral slash, 1¾ inches away, was necessary to relieve tension and served to admit a drainage tube.

Antiseptic compresses were applied and the sponge removed from the larynx by the mouth. The patient made a very comfortable recovery with primary reunion throughout. The tracheal tube was removed on the fifth day, and he was allowed to talk at the end of a week. He left the hospital with a perfectly solid larynx—and excellent phonation, which has been maintained.

DR. ABBE remarked that it seemed to be the general impression that this class of cases could not be cured.

THE PRESIDENT asked to what cause this supposed impossibility is attached; whether it is simply a mechanical one.

DR. ABBE thought it was owing to the air in respiration which broke down the union.

NEWS ITEMS.

[illegible] to Mrs. [illegible] all the friends of the late Dr. Pavy will be glad to hear that the Secretary of the Interior has reversed the decision of Commissioner Black on the claim of Lela Pavy, widow of Dr. Octave Pavy, late acting Assistant Surgeon, U. S. A., under contract with the Greely expedition, who died of starvation at Cape Sabine, about June 6, 1884. She is granted $17 per month. The Secretary holds that though Dr. Pavy's contract had expired he was still in the service.

A CERTIFICATE OF DISABILITY, issued by Dr. A. Y. P. Garnett to a government employee, was returned by a United States pension officer, with the demand that the doctor should strengthen it with implicit information. Dr. Garnett declined to furnish this information, on the ground that it would involve the violation of professional obligations. In this decision he has been sustained by Secretary Lamar, who has thus established a precedent which petty courts and government officers will not presume in future to set aside.

PROF. CHEVREUL, the chemist, is about to resign his public offices and retire to Dijon to live with his family.

THE CHOLERA.—Ever since cholera first made its appearance at Toulon in June, 1884, it has, like a spectre, been hovering over Southern Europe. Fortunately, but for no well-defined reason, it has not extended to Northern Europe, although for three seasons it has been threatening to do so. In a recent number of the *Journal* [illegible] havoc which cholera wrought in 1884 and 1885; and from that summary it may have been observed that the disease, once started at Toulon and Marseilles, seemed to radiate northward to Paris, and eastward throughout the Italian Peninsula; whilst Spain, to the southwest, was soon afterward invaded and terribly scourged. During the year just ended, however, the disease seems to have somewhat changed its point of attack, and has centred more particularly in the western and northern shores of the Adriatic, whence it spread north-eastward through Carniola and Croatia, to Agram, Raab, Pesth, and Szegedin; and south-eastward to Priedor and Novi in Bosnia, Belgrade in Servia, and even Tirnova in Bulgaria.

Cholera in Italy.—During December, 1885, sporadic cases were reported from Venice. This prevalence continued until the end of April last, by which time 116 cases and 80 deaths had occurred in the city since the beginning of the year. Early in May a sudden and rapid increase took place in the number of cases, and in the first week of June as many as 218 cases and 132 deaths were reported. The disease continued in Venice, with decreasing severity, until October, when the city was declared to be practically free from it. Altogether, not less than 1000 cases, with about 620 deaths, have occurred in the city during the past year. It may here be noted that in some quarters it was asserted that the Venetian disease was not true Asiatic cholera, whilst others describe it as "choleraic typhus." Meanwhile, however, an epidemic of undoubted Asiatic cholera was rapidly spreading in the south-eastern provinces of Italy. The disease broke out early in April at Brindisi, which is situated in a flat unhealthy locality, and by the 15th of that month 72 cases, of which 15 were fatal, had occurred in the town. From Brindisi it spread rapidly to the adjoining towns of Latiano, Francavilla, Fontana, Lecce, Bari, Barletta, etc., creating panic in the neighborhood, and anxiety in the whole country. The sanitary arrangements of these places seem to be bad in the extreme, and, at Latiano especially, the polluted wells are charged with having been mainly instrumental in spreading the disease. During the summer the towns of Chioggio, Treviso, Padua, Ferrara, Ravenna, and others in the valley of the Po, and in the neighborhood of Venice, suffered somewhat severely from choleraic sickness. A few cases occurred at Torre Annunciata, near Naples, early in September, and at Rome in October. In September, Sardinia was invaded, but, although the disease was virulent in character, it does not seem to have diffused itself widely in the island. In the middle of October, cases were reported from Genoa, and further cases followed during November; but no cases appear to have occurred in the town, or, indeed, in the whole peninsula, since the 27th of the last mentioned month. It is estimated that up to the middle of October, when cholera as an epidemic may be said to have come to an end in Italy, 21,000 cases and 8650 deaths had occurred throughout the peninsula. Some towns of Italy seem to have profited by their past experiences of cholera, and by the teachings of the Roman Sanitary Conference of last year. In Rome itself nearly all the wells have been filled up, and a wholesome supply of water provided, much to the benefit of the public health. Naples also seems to be improving its hygienic conditions. But at Florence, where it is as-

serted that the well-waters are very generally grossly polluted, and that cesspools of the worst sort prevail, there seems still to be great reluctance to effect the needed sanitary improvements.

Cholera in Austria-Hungary.—In December, 1885, occasional cases of cholera were occurring in Trieste, a town of about 135,000 inhabitants, situated at the extreme north of the Adriatic Sea, and of special importance as constituting the centre of Austrian foreign commerce. The disease died out in this town about Christmas, 1885, but broke out again on June 7th last, and from this centre rapidly spread through Fiume, Istria, Carniola, Gorizia-Gradisca, Croatia, and Dalmatia, and into Bosnia and Servia. It is officially reported that, up to the middle of November, when the virulence of the epidemic may be said to have passed, about 900 cases, and 550 deaths, occurred in Trieste alone, and that in the province of Istria 672 cases, and 374 deaths, had occurred. Bad hygienic conditions prevail in all these districts. In some places the populace are reported to have been guilty of acts of barbarism, such as were common last year in Spain. They accused the local doctors of poisoning them, and in some cases actually resorted to violence. On September 12th cholera broke out in Pesth, where its advent had for some time been dreaded. It rapidly spread, owing to the execrable sanitary arrangements of the town, and before it died out, about November 20th, more than 1200 cases, and 500 deaths, had occurred. Very severe censures were passed on the unpreparedness of the town to resist the cholera. The water-supply was described as being at all times indifferent in quality and inadequate in quantity, and it was said that over 30,000 of the inhabitants—a tenth of the total population—lived in damp underground rooms, where ventilation, a proper supply of water, and cleanliness were impossible. The town of Raab, which is situated on a tributary of the Danube, and half-way between Pesth and Vienna, and Szegedin, which is about 100 miles south-east of Pesth, suffered to some extent at the same time as the Hungarian capital. As in the case of Venice, some doubts have been expressed as to whether all the cases at Trieste returned as "cholera" were cases of the true Asiatic disease, and it has been noticed as a significant fact that during the summer no cases of diarrhœa or dysentery were recorded in Trieste, although those diseases are usually common there.

Cholera in Spain.—Spain has suffered comparatively little this year from cholera. In January the disease was still lingering in Malaga and Algeciras, where it had caused such great mortality during the previous summer; and during the first three months of the year a considerable number of cases occurred at Tarifa, not far from Gibraltar. But the disease seems then to have disappeared from Spain until October, when a fresh crop of doubtful cases was reported from Malaga.

Cholera in France.—France also has had but little cholera this year, but the little it has had, occurring as it did in the Department of Finistère, close to our own shores, has had especial interest for England. No cases, so far as is known, have occurred in Finistère since May last; but during the first four months of the year the disease undoubtedly prevailed to an appreciable extent at Brest, Concarneau, Douarnenez, Audierne, and other places in that locality.

Cholera in Japan and the Corea.—Whilst we have been watching the progress of cholera nearer home, the disease seems to have been ravaging the greater part of the Corea, and to have caused great mortality in Japan. Exact statistics are not yet obtainable, but it is reported that in Japan not less than 50,000 persons have been attacked, and 35,000 have died; whilst in Corea the population has been decimated.

Cholera in India.—India, the home of cholera, is never free from the disease; but during the past year there does not seem to have been any exceptional prevalence—at least in the three principal towns. As regards Calcutta, the fortnightly official returns during the first ten months of the year showed, as a rule, a mortality under the average of the previous five years; but since October 25th there has been a rapid and considerable increase in the cholera mortality in that city. From January 1st to December 8th, altogether 1553 deaths from cholera had occurred in Calcutta, as compared with 1836, the mean for the same period of the preceding quinquennium. In Bombay, during the same period, only 15 deaths occurred, as compared with 510, the mean of the same period of the previous five years. No deaths seem to have been recorded in Bombay during the months of July and August, and none since September 29th. In Madras, no death had been recorded since February 13th last.—*British Medical Journal*, December 25, 1886.

MEDICO-LEGAL QUESTIONS IN RELATION TO THE LAW OF DIVORCE.—The medical witnesses in the Colin-Campbell case, which has unfortunately occupied so much of the public attention, have been subjected to much and severe animadversion by counsel on grounds which appear to be entirely without foundation. The medico-legal aspects of the case raised some new questions of considerable importance, and the decisions in this and the previous trial establish conclusions not previously arrived at in any case hitherto tried.

The medical evidence was given throughout on both sides with great judgment and scrupulous accuracy, and appears to leave no room for cavil. From the facts stated in evidence, it appears that the husband had been operated on, both before and after marriage, for perineo-urethral fistula, due to gonorrhœa contracted in earlier life. In consequence of the condition of the husband, marriage was not consummated until four months after the ceremony. A fortnight after this consummation the wife suffered from a persistent vaginal discharge. She subsequently suffered from an attack of cellulitis. After she had recovered from this, the husband proposed to resume cohabitation; the wife refused, and ultimately appealed to the Court for protection. The trial took place in 1884, before Sir James Hannen, who, having heard the evidence of all concerned and numerous skilled witnesses, considered that she should be protected; the jury agreeing to that view, he gave judgment accordingly. This was appealed against, but the upper Court confirmed the judgment. This judgment was novel and important; it established this point, that the result of a former specific attack continuing, and being liable to injure the wife, would entitle her to a judicial separation. And it may, perhaps, be assumed that the same rule would hold good for both sexes. It appears that the judge did not

require, in order to establish "cruelty," that there should be a recent specific infection. In this case, the surgeons called considered that pus would run along the urethra in cohabitation, and this they held would be fraught with danger; this view is in accordance with all modern teaching. Gynecologists recognize that serious inflammatory attacks, and irritations of the genital tract are liable to follow cohabitation with those who have had gonorrhœa, although all specific conditions have disappeared. This judgment is far-reaching, but was, during the second trial, held to be a good one, which could not be disturbed. The question naturally arises, What length of time elapses before a specific attack (gonorrhœa) can wear itself out? This question did not affect the judgment above mentioned; but it is of much practical interest, and, in view of this judgment, important.

In the second trial, attempts were made to reopen the case, but these were checked by the judge. Another theory was, however, put forward as a possible explanation of the cellulitis; this was a suggested miscarriage shortly before the inflammatory attack. The consultant, however, who saw the case seven days after this was alleged to have taken place, not only did not find the slightest evidence of miscarriage, but, on the contrary, found the os and cervix in accordance with the nulliparous state. Later on in the case, in dilating the cervix, it was ascertained to have the characters of congenital stenosis. The evidence on the other side was largely based on the suspicions of a nurse who *thought*, from the occurrence of severe pain and a free hemorrhagic discharge, that a miscarriage had occurred—a suggestion negatived by the medical evidence and easily rejected by both judge and jury. Every medical man is aware that cellulitis is very frequently associated with severe pain and free discharge, and the freer the discharge the less the internal swelling, this being nature's mode of relief. This and other phases of the case emphasize anew the risks which beset practitioners in their daily work, and the necessity for the strictest observance of professional discretion in their relations to patients of whatever position in life.—*British Medical Journal*, December 25, 1886.

THE MONTEFIORE HOME FOR CHRONIC INVALIDS took in last month close upon $180,000 at its fair in the N. Y. Central Park Garden in two weeks.

THE LIBRARY OF THE LATE FRANK HASTINGS HAMILTON, M.D., LL.D., has been sold to Dr. John B. Hamilton, Supervising-Surgeon-General U. S. Marine Hospital Service, Washington, D. C. The specimens have been purchased by the U. S. Army Medical Museum. The original specimens, of which illustrations are given in the doctor's world-renowned and classical work *On Fractures and Dislocations*, are to be found in this collection. The instruments were sold at private sale.

NOTES AND QUERIES.

[redacted]

was not removed from the curb. Horses were watered from this well. In his journeys back and forth from the stable, the hired man did not properly clean his boots of manure, etc.; hence the snow on the curb and adjacent ground was polluted. In consequence of the thaw the polluted snow and ice, as it melted, percolated through the cracks in the wooden curb. The water of the well was examined, with the following result:

Color, yellow; taste, good; turbidity, marked; odor, ammoniacal.

[redacted]

Suspended solids	1.000
Volatile matters after incineration and recarbonating	9.500
Sodium chloride	8.445
Magnesia	0.627
Calcium carbonate	9.140
[redacted]	[redacted]
Silica	1.540
Total solids upon evaporation	30.000

The solids, upon incineration, turned intensely black. From lack of time, "free and albuminoid ammonia" were not ascertained. The water was condemned on the authority of Parkes, who says, "Of the solids, not more than about one grain per gallon (1.04 per 100,000) ought to be volatile, or capable of being driven off by a red heat. The solids should blacken very slightly on ignition."

Careful investigation has convinced me that the danger of contamination from the above mentioned source cannot be overestimated. I have repeatedly witnessed accumulations of polluted snow around wells. The necessity of keeping well curbs free from such filthy accumulations would seem to be self-evident.

CHARLES E. FAIRMAN, M.D.

[redacted]

SIR: In a lecture by Dr. Bartholow, in your issue of December 18th, on "Electro-therapeutics," I notice errors of statement which are, it seems to me, deserving of correction. He says, I doubt not with all honesty of intention, that "general faradization first proposed by Dr. Beard;" and further on, "Central galvanization, which we also owe to Beard," etc. Dr. Beard is dead, it is true, and cannot speak for himself, but he was my friend, and I should be the last to detract in any way from the credit due him. I recognize the fact that Dr. Bartholow's lecture was probably given in an offhand clinical manner, and could not therefore be expected to abound in that accuracy of statement in small matters that we look for in written productions; but he will agree with me that whatever is worth saying at all is worth saying with exactness, and will pardon this note of correction. Central galvanization is perhaps due to one no more than to the other; our book certainly gives credit to neither over the other. As regards general faradization, however, the first formal presentation of it appeared in an article of mine published in the *Medical Record* in 1876, and in our work on the *Medical and Surgical Uses of Electricity*. The idea of the constitutional tonic effects of electricity and the method of general faradization by which these effects are obtained are distinctly attributed to me, and with Dr. Beard's full knowledge and accord. Yours respectfully,

A. D. ROCKWELL, M.D.

NEW YORK.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 4 TO JANUARY 10, 1887.

CORSON, J. K., *Captain and Assistant Surgeon.*—Ordered to Fort Cœur d'Alene, Indian Territory.—*S. O. 227, Department of Colorado*, Dec. 31, 1886.

MUNN, C. E., *Captain and Assistant Surgeon.*—Ordered to Fort Canby, Wyoming Territory.—*S. O. 227, Department of Colorado*, Dec. 31, 1886.

BANISTER, J. M., *First Lieutenant and Assistant Surgeon.*—Ordered to Fort Cœur d'Alene, Indian Territory.—*S. O. 227, Department of Colorado*, Dec. 31, 1886.

IVES, F. J., *First Lieutenant and Assistant Surgeon.*—Granted one month's leave of absence, with permission to apply for twenty-three days extension.—*S. O. 1, Department of the Platte*, Jan. 3, [illegible].

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. L. SATURDAY, JANUARY 22, 1887. No. 4.

ORIGINAL ARTICLES.

ON THE USE AND ABUSE OF PASSIVE MOTION.[1]

BY HENRY B. SANDS, M.D.,

SURGEON TO THE ROOSEVELT HOSPITAL, NEW YORK.

I AM induced to bring before the Society for discussion the well-worn, but important, subject of passive motion, in the hope of putting it, if possible, on a broader and more scientific basis. So many claims are made in its favor which seem to me to be unfounded, that I think it desirable to state just what amount of good may be expected from it and in what class of cases the method is unsuitable. I approach the subject with some hesitation because I am apprehensive that my opinion will encounter opposition. I shall present, however, little more than the results of my own experience, and I entertain some views which I should be glad to alter provided I could find other ones supported by credible testimony.

The phrase passive motion may appear to be somewhat ambiguous, as the word passive implies merely that the patient either offers no resistance to manipulation, or that the resistance offered is overcome. On the other hand, the movements made by the surgeon are always active and sometimes very forcible. A degree of severity, therefore, may belong to the procedure, which the term is not adapted to convey.

Concerning the common form of injury known as a sprain, which most often occurs at the ankle, it may be remarked that various lesions are doubtless included under this designation. In slight cases the ligaments are, perhaps, only severely stretched; in bad ones they may be more or less completely torn. Subcutaneous extravasation of blood is usual, and occasionally hemorrhage takes place into the adjacent joints and tendinous sheaths. In a few cases the parts continue weak and painful for a considerable, or, it may be, an indefinite period of time; while, in a still smaller number, the foundation is laid of serious organic disease.

In no form of injury do wider diversities of opinion exist regarding treatment than in that called sprain. The old-fashioned treatment, which prescribes rest and fixation of the sprained joint, is preferred by some; while wonderfully good results are declared by others to proceed from the early employment of massage combined with passive motion and the almost immediate use of the injured parts. As in many other instances, the truth here probably lies between the extremes. My own practice has generally been conservative. Unless the injury is of trifling degree, rest and immobility would seem to be instinctively, if not imperatively, demanded. By rest and immobilization an opportunity is afforded for a reunion of the ruptured parts, while the pressure of the bandage favors the diffusion and absorption of blood, serum, and other extravasated fluids. When it may be reasonably presumed that the injury has been repaired, usually after the lapse of from one week to two weeks, passive motion has seemed to me to be useful by preventing or removing stiffness or pain. Aside from tuberculous disease of the joint, which may undoubtedly arise in consequence of this form of injury, I have often known the use of a badly sprained ankle to be followed by long-continued lameness and pain. I, therefore, am inclined to be cautious and to enjoin rest for perhaps an unnecessary period rather than to recommend motion which might be premature. Massage and passive motion I have found most serviceable in recent sprains of mild degree, and in cases of stiffness resulting from old adhesions or prolonged disuse. In such instances I have witnessed excellent effects from these remedies, but I am disposed to look with distrust upon active treatment applied to recent strains at all severe. I have been reminded by Dr. Wm. G. LeBoutillier, lately my House Surgeon in the Roosevelt Hospital, that a favorite method there, when the sprain is not severe, consists in the immersion of the injured foot for several hours in hot water, and the subsequent application of a firm bandage. Under this treatment many patients are enabled to leave the hospital, walking tolerably well at the end of three days.

After the reduction of dislocation I have rarely found it necessary to employ passive motion. I have usually kept the injured parts quiet by means of a sling or a bandage for a period varying from a week to a fortnight, and have then encouraged the patients to resume the normal movements. In a few instances, after reducing dislocation of the shoulder, I have been obliged to use considerable force, in order to break up adhesions which had formed outside the articulation, in consequence of inflammation caused by the primary injury.

Experienced surgeons are divided in opinion regarding what mode of treating fractures is least likely to be followed by stiffness. Fermentil maintains that immobilization never induces ankylosis, but tends to prevent it by averting inflammation. Other surgeons are so apprehensive of causing, by immobilization, a loss of movement that they recommend almost entirely the use of splints, and practise very early passive motion. Both parties claim that they have obtained good results; and without pretending to be dogmatic, I desire to state my own views as founded on personal observation.

In the first place, cases of true ankylosis of the kind I can recall are those in which comminution had

[1] Read before the New York Surgical Society, Dec. 27, 1886.

taken place of the bones composing the ankle- or the elbow-joint, which had become fused during the process of repair. Provided a fracture is simple comminuted, however extensive, it is not very likely to be followed by ankylosis, and, at the present day, with suitable antiseptic treatment, such a result should be infrequent even when joint fractures are compound.

But if true ankylosis after fracture is rare, stiffness from false ankylosis is less uncommon, and, if incurable, may greatly diminish the usefulness of a limb. Its nature and causes are various. Undoubtedly it may occur in joints from simple disuse. I remember an example of the kind which I met with many years since, while I was serving an apprenticeship in the Bellevue Hospital. A woman broke her left femur at about its middle three times in the course of eight months. During the whole of this period she was kept in bed with the limb maintained in a straight position by means of a weight attached to the foot. Meanwhile the knee, which was remote from the seat of fracture, became so rigid that, even with the aid of an anæsthetic, only the slightest motion was possible. She was dismissed with a stiff joint.

That organic changes occur in such cases cannot be questioned. Shortening and rigidity of the capsule have been conjectured to exist, while distinct pathological conditions have been described by Bonnet[1] and Toussaint,[2] who found, on post mortem examination, or on inspecting limbs which had been removed by amputation, effusion of blood within the affected joint, undue redness of the synovial membrane, newly formed connective tissue uniting opposed articular surfaces, and swelling, erosion, and adhesion of the articular cartilages. Moreover, Menzel[3] has shown by experiment that in animals, swellings, hyperæmia, and pterygium-like affections of the synovial membrane, and degenerative changes in the articular cartilages often take place in consequence of the enforced rest of a joint. Examples of the kind referred to may be seen or may have been met with by every surgeon present, but they are seldom grave enough to cause serious apprehension. Furthermore, they are rare. As a rule, I have not observed that long-continued immobilization of a healthy joint gives rise to any stiffness which cannot be quickly overcome, either by passive motion or by the unaided efforts of the patient. The early retention of the natural movements and the absence of a sharp inflammatory reaction when those are removed, prove that no important lesions have occurred. Nevertheless, the occasional sequel of obstinate stiffness suggests the propriety of watchful examination and the avoidance, by timely passive motion, whenever necessary, of the injurious consequences that might otherwise ensue.

False ankylosis after fractures is usually dreaded when the fracture complicates a joint, or when it is situated very near to one. But I am satisfied that the danger in such cases has been greatly exaggerated, and that the stiffness, when it occurs, is often erroneously ascribed to the presence of morbid adhesions. In many examples of fracture at the elbow or at the ankle, the subsequent limitation of motion can be traced to some bony displacement which happened at the time of the injury, and which was not accurately reduced. Or, as we have all noticed, the displacement may recur even after reduction has been accurately effected. Again, in some instances, a bony callus may impede motion by projecting into the interior of a joint. Impediments of the kind referred to are often discovered only at a period after the swelling of the soft parts has subsided. The ankylosis in the first two mentioned sets of cases does not depend on the formation of adhesions, but on a faulty position of one or more of the bony fragments. It cannot be attributed to the long-continued wearing of splints, except so far as they may hide from view the existence of the impediment, and lead the surgeon to believe that things are right, whereas they are wrong. Whenever any such uncertainty is met with, therefore, I am in the habit of frequently examining the injured parts, and of resorting, if necessary, to such manual force as will restore the fragments to their proper positions. Here passive motion will often be expedient, both as a test and a remedy; but it is not practised with the intention of rupturing abnormal adhesions. At a later period, when consolidation has taken place, and motion is prevented by bony prominence, the ankylosis must be overcome, if at all, by some form of cutting operation. Passive motion, although often tried in these circumstances, would be obviously improper.

Adhesive inflammation, mainly periarticular, I believe to be the chief agent in producing the stiffness due to false ankylosis following fractures. Fortunately, this affection rarely occurs to any troublesome extent when fractures are judiciously managed, and the broken bones are held in position by splints which do not exercise undue pressure. Accordingly, much stiffness of a joint seldom follows the usual treatment of fracture, which involves keeping the parts immobilized for three or four weeks.

Even after the patella has been fractured, and the knee has been confined in a straight position for a period of eight weeks, the joint is sometimes supple almost immediately after the splints are removed; and, without artificial assistance, will allow full flexion after the lapse of several months. Believing that adhesive inflammation is rarely severe after fractures in the neighborhood of joints, or extending into them, I have not feared the occurrence of ankylosis, but have generally avoided making movements before the consolidation of the fracture. So far as my experience goes, I have never had occasion to regret having followed this practice, and have never known ankylosis to result from it. Early motion, in my opinion, is very apt to be premature, and to cause the very stiffness it is intended to prevent. The case is different, however, when inflammation, denoted by pain, swelling, and œdema, has actually set in. It may be argued that at this period the plastic material is soft, and that, by passive motion, the formation of adhesions, and the consequent stiffness, may be avoided. But even here my practice has nearly always been mild and conservative. By

[illegible] Inaug. Diss. [illegible]

removing pressure, by keeping the injured parts at rest, and by making cold external applications, I have sought to control the existing inflammation and to limit the amount of fibrinous exudation. To anticipate one evil of the effect of ankylosis, however, I have in these cases been careful to place the joint, if possible, in such a position as will render the limb more serviceable in the event of subsequent stiffness. Passive motion I have seldom practised under these conditions, because it has appeared to me that it might do harm. Indeed, while the parts are swollen and tender, motion is difficult and painful, and if perseveringly made, is liable, according to my experience, to cause an aggravation of all the unpleasant symptoms. On this point, however, I desire to speak with some reserve, because I have very little actual knowledge concerning the effect of passive motion practised under the circumstances described. I have found it to be extremely painful, and I have suspected it to be mischievous. This is all I am willing to say. After operation for correction of the deformity caused by Dupuytren's contraction of the fingers, and after plastic operations on the hand, I have usually resorted to passive motion within a week, and have thought that stiffness was thereby prevented. Now a similar rule may apply to fractures, when threatened with ankylosis; but I have not had any experience which would convince me that such is the fact.

In common with many other surgeons, probably, I have met with stiffness most often after fractures of the lower end of the radius. I have seldom seen it except in persons who had passed the middle period of life, and I have never known it not to be preceded by signs of inflammation, which I believed to be adhesive in character, and to involve especially the sheaths of the tendons in the neighborhood of the wrist. Certainly the stiffness which occasionally follows is due rather to adhesion of the tendons than to any affection of the joints. The liability to this unfortunate occurrence has led some eminent surgeons to discard altogether the use of splints in the treatment of these fractures, and to seek to prevent stiffness by an early resort to massage and to active and passive motion. I am not prepared to condemn such treatment entirely, or to deny that it may sometimes be expedient. But I am unwilling to believe that it is usually either necessary or safe. Some of the worst results I have witnessed have followed a neglect to fulfil the ordinary indication to reduce the displacement, and to maintain the reduction by the application of suitable splints. Not only deformity, but also loss of motion, may follow such neglect, and I am sure that a proper reduction of the fragments will go far toward preventing the occurrence of inflammation, on which the stiffness ultimately depends. It can be conclusively shown that immobilization of the injured parts may be usually enforced for a long time without giving rise to ankylosis. At the Roosevelt Hospital, where many fractures of the lower end of the radius are treated, the plan adopted is to reduce the displacement at once as far as possible, and to apply two straight wooden splints, which extend along the forearm and the hand, but not so far as to impede the movement of the fingers. These splints are occasionally removed for the purpose of examining the parts, which are otherwise allowed to remain undisturbed for a period of four weeks. The splints are then dispensed with, when the bones are found to be firmly united, the freedom of motion being only slightly impaired. The results they obtain are excellent, and the normal movements are soon regained.[1] Two hundred and twenty-seven cases have been treated according to this method during the past three years, and only one case has terminated in permanent stiffness.[2] It may be fairly claimed, therefore, that, as a rule, these fractures can be successfully treated without resorting to early passive motion. Moreover, the fact that such fractures commonly get well without stiffness, when the surgeon early begins passive motion proves nothing in favor of it, because they might have recovered equally soon if this had been omitted. But we must admit that stiffness now and then occurs; and the problem to be solved is how this can be obviated. I frankly confess that I am unable to offer, under all circumstances, a sure remedy. When the patient is old and rheumatic, the injury severe, and the inflammation active, I believe that stiffness may follow, whatever plan of treatment is pursued. I should be careful in such a case to remove all pressure of splint which might increase the existing inflammation, and to combat the latter by rest, elevation of the limb, and by making cold applications to the tender and swollen parts. Passive motion I should defer until the acute stage had subsided. An early resort to the latter method while active inflammation is in progress, I have never dared to prescribe, fearing that it might cause harm. If I could be convinced from the experience of my colleagues that such a practice is beneficial, instead of injurious, I should be glad to change my present opinion, and to renounce the plan of treatment which I have found generally, if not uniformly, successful.

I can speak much more positively and favorably respecting the efficiency of passive motion in promoting convalescence after fractures, by removing what are called their residua, namely, swelling, stiffness, and pain in attempting movement. Often, it is true, these symptoms are not very marked, and will disappear entirely if the patient is encouraged to use the limb. But, when they are decided and persistent, and when the natural movements are shunned on account of pain, indolence, or timidity, the value of massage and passive motion is unquestionable. When practised daily, or every second day, such treatment will frequently cause rapid improvement, by rendering the circulation in swollen parts more active, by dissipating the swelling, which is usually due to passive œdema, and by making motion easy and painless. As every surgeon knows, patients who have suffered from fractured limbs are often reluctant to use them, even after the bones are firmly

[1] I am indebted for the statistics to Dr. C. H. Huntington.

[2] The patient referred to was a man who was treated in the usual manner, soon after the accident. He remained away from the hospital, contrary to instructions, for a period of three weeks; when he returned his wrist was found to be stiff. No further particulars are contained in the report.

united, and it is in this class of cases that friction and passive motion are so valuable. Not infrequently, indeed, physicians, as well as patients, are deceived by the idea that the symptoms are indicative of inflammation, which requires rest; and for this reason patients are sometimes disabled for a long period, and possibly treated for rheumatism or for some other disease which does not exist. A few active manipulations will reveal the error in diagnosis, and not seldom accomplish a cure. The sudden disappearance of pain on motion which is occasionally noticed in these cases, can hardly be otherwise explained than by supposing that abnormal bands or adhesions have been forcibly ruptured. Whatever be the rationale of the treatment referred to, there can be no doubt that it is eminently successful.

In a small number of cases of stiff joints following injury, or dependent upon long fixation of a limb, I have derived great advantage from the employment of an anæsthetic. The absence of pain and of muscular contraction thereby induced, facilitates the necessary movements, and occasionally affords valuable aid in diagnosis. As a rule, however, anæsthetics may be dispensed with, and, furthermore, repeated movements are commonly needed to obtain the desired result.

I possess no personal knowledge of cases of slipping or adhesion of tendons, or of mysterious or unexplained lesions which, having resisted the ordinary means of treatment, have been brought to speedy recovery by the rough handling of bone-setters, and I believe that most of the statements made regarding their achievements are, to use a mild term, *inaccurate*. I am incredulous and suspicious of all marvellous cures, whether claimed to have been wrought by the bone-setters, or by members of the medical profession.

I have met with little or no success when applying passive motion for the purpose of overcoming the firm contractions of the skin and deeper tissues which follow burns and other injuries accompanied with much loss of substance. The limit of stretching of which scars are capable by passive motion is soon reached, and further attempts to extend them are quite liable to cause rupture.

The value of passive motion as a means of overcoming ankylosis due to disease not caused directly by injury is a subject which admits, perhaps, of but little discussion. But there are some facts relating to it which should be distinctly stated, and there are some errors prevalent which should, I think, be corrected. Among the severer affections of the kind referred to, I have found most amenable to treatment cases of stiffness of the shoulders, apparently unconnected with disease of the joint, but dependent upon the pressure of adhesions in the large bones situated beneath the deltoid muscle. This disease, which has been well described by Duplay, has many features resembling those due to arthritis, from which, however, it is not hard to distinguish. But the movement of the arm at the shoulder-joint may be limited and painful, and the usefulness of the limb nearly lost. I have encountered many such cases, and have invariably succeeded in affording relief by the employment of passive motion. This I have always practised after administering an anæsthetic, and I have sometimes been compelled to resort to considerable force in order to overcome the resistance. The adhesions, wherever situated, usually give way with an audible sound, and the freedom and extent of motion are completely, but sometimes only temporarily restored. By the subsequent use of passive and of voluntary motion and by repeating the manipulations while the patient is under ether if necessary, I have seldom failed to obtain a complete and permanent cure.

Unfortunately, I am unable to record equally good results from the treatment by passive motion of any other form of ankylosis, if I except certain cases of hysterical muscular contraction, which may be dismissed with this bare allusion. Most often I have had occasion to employ passive motion with the simple, but unfortunate, result of putting the diseased limb in a suitable position. Even before such an attempt is made, however, discrimination and caution are sometimes necessary. Probably most surgeons would agree that when true bony ankylosis exists, passive motion should not be made to correct the deformity, which should be dealt with, when necessary, by the use of the knife and the saw. Passive motion may also fail to alter the position which a limb has assumed in the course of tubercular arthritis of long standing. When, in old hip disease, the thigh has become much flexed and adducted, forcible motion, intended to secure a straight position, is at least a doubtful expedient. It will probably turn out to be unsuccessful, because the soft parts will be found so contracted and rigid that nothing short of actual violence will cause them to yield enough to permit a correction of the deformity, which, moreover, may be further maintained by bony alterations, impossible to anticipate or overcome. Again, the employment of much force, in such circumstances, has often been known to set up severe inflammation with even fatal consequences. Excision, therefore, although apparently a harsher remedy, would seem to be preferable, as involving less danger, and obtaining a better and more definite result. Similar remarks may be made respecting the knee, when, in consequence of old joint disease, the leg may become flexed and rotated outward, the head of the tibia partly dislocated backward, and the soft parts behind the joint contracted, any attempt to straighten the limb by passive motion, even when preceded by tenotomy of the hamstrings, will be futile, and the end in view will be gained only after a formal incision has been performed. But in the early stage of arthritis, whether tubercular, gonorrhœal, rheumatic, or of other origin, a bad position can always be safely corrected by manual force, aided by an anæsthetic, when necessary, and thereby, in the event of ankylosis, one of its most disastrous consequences can be prevented.

For the purpose of restoring movements which have been impaired or lost from the occurrence of firm false ankylosis of the joint from whatever cause, or for the removal of stiffness dependent on the firm adhesion of tendons to their synovial sheath, my results, after many trials of passive motion, have been

so discouraging that I can seldom advise this mode of treatment as a means of cure. As, however, the exact amount of resistance to be overcome, and the exact pathological condition cannot be settled beforehand, I almost invariably, when consulted in cases of the kind referred to, advise the administration of ether, and the trial of a fair amount of forcible manipulation. But if the adhesions are numerous and firm, and great force is required to establish mobility, I have found that even when the movement becomes very free and extensive, at the time of operation, they are lost again almost immediately afterward, the stiffness returning, and being as bad as before. It is often said that, in these cases, failure is due to a neglect, on the part of the surgeon, to maintain the advantage already gained by the continued practice of passive motion. But I am convinced that the assertion is untrue. So much pain, swelling, ecchymosis follow the first attempts to move the stiffened parts, that for a day or two afterward they must be allowed to rest; and when inflammation has abated sufficiently to warrant a repetition of passive motion, the whole thing has to be done over again, and with the same result. My experience with this method in such cases has been so uniform, that I cannot doubt the correctness of the opinion I have expressed. I recall an instance in which a man, who once consulted me, was treated in the manner I have described; and although at the time of the operation the leg, which was at first extended, could be well flexed, the stiffness soon returned, and was as marked as ever. I kept the man's leg extended during his convalescence, and then advised him to let it alone. But he fell into the hands of an enterprising and enthusiastic surgeon, who promised to cure him, and who afterward boasted that he had done so. I finally caused an inquiry to be made about the patient, and ascertained that the joint had soon become again immovable.

To sum up what I have said, I am not an advocate of passive motion, except under the restrictions which I have endeavored to define. I believe that when practised without discrimination, it will often be unsuccessful, and sometimes injurious, by inducing an increased inflammation. I am certain that the severe forms of ankylosis and of fixation of tendon are frequently due to this disease, and that the inflammation will be aggravated by employing passive motion before the active symptoms have disappeared. The idea that motion will always prevent ankylosis is a fallacy which is contradicted by common experience. I have performed the operation of incision of the elbow for the cure of true ankylosis, and I have seen operations performed by others, during which, perhaps, too little bone was taken away; and, in spite of the early and diligent use of passive motion, the stiffness has returned, bony consolidation has recurred, and the operation of excision has had to be repeated. But motion may be successfully employed as a means of causing a bony deposit to take place. It is a well-known fact that, in many instances of ununited fractures of the thigh or of the leg, bony union may be determined by the inflammation which is got up by making forcible motion of the fragments, or by causing the patient to walk about upon the injured limb, with the view of pressing them against each other. On the other hand, by operating according to modern antiseptic methods, which tend to prevent inflammation, partial incision of even so intricate a joint as the elbow may sometimes be performed without any impairment of mobility. I have brought the subject of passive motion to the attention of the Society because it is one of great practical importance, about which surgeons are frequently consulted, and about which there may be honest difference of opinion; but, as I mentioned in the beginning, I should be glad to change some of my present views, if others could be advanced which are sustained by evidence that appears to me to be clear and trustworthy.

SOME CASES OF SUDDEN DEATH UNDER ETHER.

BY J. C. REEVE, M.D.,

THIS presentation of a series of cases of sudden death under ether is caused by a paragraph in the report of an "Accident with the A.-C.-E. Mixture," by Dr. John H. Packard, published in THE NEWS, for January 8th. That paragraph contains a quotation from my contribution to the American edition of Holmes's *System of Surgery*, vol. iii., and is as follows:

"Reeve, indeed, says: 'Ether, in the human subject, may produce death as suddenly, as unexpectedly, and in the identical manner that chloroform does.' But, with all respect for his authority, I must say that my own search for such cases among those recorded has been fruitless."

The words quoted were not written by me without due consideration as to what they mean, and I must accept, therefore, this expression of doubt as to their truth, as a sort of challenge to which I feel compelled to respond. Moreover, if a man so well informed as Dr. Packard has never been able to find any such cases, there must be many others, members of the profession, less fortunately situated than he is, to whom it will be good service to present some of these cases, since their importance cannot be exaggerated and their practical bearing is manifold.

A preparatory question as to what is to be considered a death from ether, demands consideration. Dr. Packard, continuing his remarks, says, "In every instance there was either previous disease or some pathological condition discovered after death, which, at least in great measure, accounted for the fatal result," and then goes on to criticise the report of a case which will be presented hereafter. He says it was a case "at first sight very like a chloroform-death; both lungs were found studded with hard cancerous nodules, the liver was adherent to the diaphragm, and the heart was fatty." The report I have says: "there were some nodules of cancer in the liver and lungs," but, either way, these could not constitute a pathological condition which would cause sudden death, neither could the adhesion of the liver to the diaphragm. There remains then the fatty heart, and I believe this is not a fre-

quent cause of sudden death, *per se;* the patient must be subjected to some powerful disturbing agent, which in this case was the ether. All I would ask in this respect is that the same considerations shall hold as to ether that would have been held had chloroform been administered. More than this should not be asked; less than this I would not accept. In the case criticised by Dr. Packard, had chloroform instead of ether been administered, I am confident that there would not have been a question raised, by any one, anywhere, that the anæsthetic agent was the determining and sole cause of death. Fatty degeneration of the heart has been frequently found after chloroform deaths, but I know of no instance in which it was made to bear the burden of the patient's death, to the acquittal of chloroform as the active agent.

But from the reports of cases which follow, every reader can judge for himself. Only such points as seem to be essential are given, for the sake of brevity, but references to the original sources have been carefully made in every instance. I begin with the first reported case of death from ether.

Case I.—Paris, July 10, 1847. Patient, male, forty-five years of age; operation for cancerous affection of left breast; "a man of tolerably robust constitution which the disease had not yet deteriorated." After an administration of about ten minutes duration, insensibility was manifest, respiration was loud, slow, but exempt from râles, and the surgeon began the operation. "The incision had scarcely commenced, and only a small quantity of dark blood had escaped, when the countenance changed, and the respiration became slow. The pulse, examined now for the first time, was soft, full, and very slow; all at once it stopped; all was over." The post-mortem revealed an extremely softened spleen, but no affection of a vital organ.[1]

Snow[2] says: "this patient appears to have died rather from the want of admission of sufficient air to the lungs than from the effects of ether. The administration had been slow and after death all the organs gave a strong odor of ether, but to attribute a death so sudden to suffocation is a woful distortion of evidence."

Case II.—Female, aged fifty-five, in very poor health: operation for tumor of superior maxillary bone, at Lyons, September 11, 1852. The operation had not proceded far, the ascending ramus had not yet been divided, when all at once respiration ceased, the pulse and beating of the heart could not be felt, and all efforts at resuscitation proved fruitless.

Snow says: "this patient evidently died of hemorrhage," yet in a full report of the case[3] by the surgeon, all that is said of this is, "I had tied some vessels upon the edges of the incision!" In his efforts to clear ether of this death, Snow resorts to most astounding logic. He says: "According to the results of my experiments on animals ether is not capable of causing the kind of death which this patient died!"[4] Therefore, belladonna could produce no injurious effects upon man because some animals can eat it with impunity!

The next four cases are taken from Kappeler's table, which contains reports of thirteen cases of death from ether. I have not access to the original reports, even of the cases which occurred in this country. The foot references are those given by Kappeler.

Case III.—Duming's case, Bellevue Hospital, New York, 1872. Male, sixty-eight years old, etherized for adjustment of fracture of thigh. In ten minutes patient was fully under the influence. After some manipulation inhalation was suspended for four or five minutes. Inhalation recommenced on account of muscular rigidity, but in one or two minutes the administrator observed the pupils suddenly dilate and respiration cease. The heart was still beating. All attempts at resuscitation failed. No report of post-mortem examination.[1]

Case IV.—Male, aged fifty-four, resection of maxilla for caries. An incision was made along the bone and four teeth extracted, when it was observed that the patient was very blue in the face. Artificial respiration and galvanism were without result. Kappeler says: "The editor of the Boston *Journal* believes that the patient was suffocated by blood in the trachea." The report of the autopsy makes no mention of this.[2]

Case V.—Dr. Sinclair's case; Boston; operation for incision of the cervix. Soon after the operation was commenced the administrator observed that the pulse was gone, and respiration had ceased. All efforts at resuscitation proved unavailing. The post-mortem examination showed Bright's disease, chronic pleuritis, and embolism of pulmonary artery. The evil influence of the former, as to the effect of ether, was not then recognized as now.[3]

Case VI.—Lowe's case; the one which Dr. Packard says is "at first sight very like a chloroform death." Female, aged forty-eight, of healthy appearance, and of tolerably strong build. Operation for removal of a mamma. After a few inhalations the patient's face suddenly became turgid and the hands white. The inhaler was at once removed, the tongue brought forward, cold water dashed over the face, and the chest rubbed with brandy; but the breathing became stertorous, the face became more and more congested, the pulse failed, there was an effort at vomiting, and death took place within a few seconds.[4]

Kappeler places this case in his table without any question or expression of doubt as to its being a death from ether.

Case VII.—Male, aged sixty-nine, much exhausted; London Hospital; strangulated hernia. There was much struggling, as the lips became blue the inhaler was removed. Respiration improved for a brief period, but remained bad. The pulse became worse and worse, and disappeared, while the breathing continued for thirty seconds. Heart flabby, the left ventricle not contracted, the lungs emphysematous, and the bronchi filled with "purulent mucus." Incarcerated hernia.[5]

The next case is published in Holmes's *Surgery*, on the page preceding the report of the case commented on by Dr. Packard, and therefore could scarcely have escaped his attention, but he does not allude to it. In a foot-note it is there stated that the case was never before published, and no names are given in connection with it. I will now say that it occurred to a prominent practitioner of Rhode Island, and the report was furnished me by my friend, Dr. Charles O'Leary, of Providence.

[1] Traité d'Anesthésie chirurgicale, Paris, 1863.

[4] Op. cit., p. 364.

CASE VIII.—Male, aged sixty-two, addicted to drink. Ether was given for examination of hips injured the day before, patient being in good condition. Two ounces of whiskey given, then ether administered to amount of three or four ounces. Patient never fully anæsthetized; pulse carefully watched. At a period not later than fifteen to twenty minutes from beginning the inhalation, "the patient suddenly, and without any symptomatic warning whatever, stopped breathing, and was dead." "Death was instantaneous," another observer writes. Post-mortem examination showed pleuritic adhesions, heart full of dark fluid blood, its muscular structure healthy; the valves, especially the aortic, affected with atheromatous deposit; liver and kidneys congested, the latter studded with cysts.

The next case occurred in Philadelphia:

CASE IX.—Male, aged sixty-seven; Pennsylvania Hospital. A feeble old man, with strangulated hernia; a hard drinker; had suffered much from exposure and want of food. After anæsthesia by ether had been kept up some time herniotomy was decided upon. Soon after the operation was commenced, a copious bronchial secretion kept filling the patient's mouth; during an effort to expel this a very large portion of the bowels was forced out; at this time the breathing became labored, and the pulse faltered, asphyxia developed rapidly, the patient expired on the table. This was evidently a bad subject for anæsthesia, and a bad subject for operation, yet, in the language of the reporter of the case, "the ether was unquestionably the immediate cause of death."[1]

CASE X.—Male, aged sixty-six years, for some weeks had abdominal symptoms, which finally culminated in complete intestinal obstruction, and right lumbar colotomy was undertaken. "There was no complicating disease in heart or lungs, . . . there was nothing to contraindicate the use of an anæsthetic, or to make one more than usually anxious as to its effect." Ether given by Clover's smaller inhaler. After five minutes the first incision was made by Mr. Pridgin Teale. In ten minutes, just as the reporter "was engaged in counting the carotid pulse, which was beating evenly, and with rather a stronger impulse than before the operation, he showed an inclination to vomit, and ejected a quantity of brownish fluid, smelling strongly of brandy. He then took one deep inspiration, and seemed as if inclined to vomit again; but his head sank back on the pillow, and he quietly died, making no further respiratory effort, except one short gasp during artificial respiration. No post mortem was allowed, but examination failed to show any mechanical obstruction to breathing. The inhaler showed that a little more than an ounce of the ether had been used."[2]

The following two cases are from a paper on "Deaths from Anæsthetics in 1885," by Ernest H. Jacobs, M.A., M.D.[3]

CASE XI.—Male, aged sixty-two years, at London Hospital. Ether given to reduce a dislocation of shoulder. "In three minutes he began to look pale, his breathing was feeble; dusky pallor increased in spite of artificial respiration. At the post mortem the lungs were found emphysematous and congested, and there was bronchitis (?). The heart was flaccid and fatty, with adherent pericardium."

CASE XII.—Girl, aged ten years, much emaciated, and looking very ill; to be sounded for a calculus. When she had taken but a few inhalations she was observed to be very pale, "the pulse ceased, the breathing continued." All efforts of resuscitation were in vain. "This," the reporter says, "is the most remarkable case of the kind I have ever known. The patient took not more than a drachm of ether, and died in a precisely similar manner to that which generally obtains in the case of chloroform."

CASE XIII.—Male, aged fifty years, suffering from severe inflammation of the bowels, due to obstruction. Ether was carefully administered preparatory to an operation. He inhaled it without the slightest hesitation or discomfort, but he had not taken more than three or four inhalations when he fell back, breathed once or twice, and died. At the post-mortem examination there was found considerable purulent effusion in the peritoneal cavity; at the lower part of the descending colon was a malignant mass of the size of small cocoanut, blocking the canal. In the right ventricle of the heart was a fibrinous clot attached to the tricuspid valve. The medical men did not think the patient died from the ether, because death occurred so very early in the administration. The post-mortem failed to explain so sudden a death without the ether as a factor.

This collection of cases is not presented as complete; I am very certain that it is not so. To make it I have not gone beyond the limited resources of my own library. I have not given any cases in which death, evidently due to ether, took place at a period more or less remote from the administration. There are many such on record. Nor will I extend this paper by presenting cases in which dangerous symptoms occurred under ether; just such symptoms as Dr. Packard's patient had from the A.-C.-E mixture. I have kept closely to my text: "*Ether in the human subject may cause death as suddenly, as unexpectedly, and in the identical manner that chloroform does.*" Whether the evidence adduced sustains the proposition or not, must be left to others to determine. If, however, the ground be taken that the cases adduced did not die from ether, then it is incumbent upon the objector to show what they did die from.

Finally, I wish to disclaim, in the most emphatic manner, any feeling of partisanship in this matter. I have no "case" to make out against ether. I have no anæsthetic to advocate as perfectly safe, for such a thing does not exist. I am ready to admit that, *probably*, ether is the safest anæsthetic we possess for general surgical purposes. I am ready to assent to the proposition that, *theoretically*, any mixture of anæsthetics increases in danger, in proportion as chloroform is added to it. But when it comes in practical life to a decision between ether and the A.-C.-E mixture, I choose the latter, because of a lifetime experience with it, because of great practical advantages to the surgeon, and far less unpleasantness to the patient, while its greater danger has never yet been shown. Mathematically, it never can be shown, because the relative number of administrations cannot be learned. Three times I have seen dangerous symptoms from its use. One case has been very briefly published.[1] In one of the others the danger was soon over. In the third, after the patient had been brought around, the A.-C.-E mixture being exhausted, a small quantity—ʒss—of chloroform was administered in order to

complete the operation. This was speedily followed by a condition so strikingly more dangerous, and from which it was so much more difficult to restore the patient, that all concerned were very well satisfied not to give any more anæsthetic. If now, on account of this experience, the A.-C.-E mixture is to be abandoned, it must be in favor of an agent which has caused the deaths presented in this paper, besides many others in which death occurred later, and which has over and over again caused dangerous symptoms, such as the A.-C.-E mixture caused under my observation and in the hands of Dr. Packard.

HERNIA INGUINO-PROPERITONEALIS WITH AN ACCOUNT OF A CASE.[1]

By CHARLES W. DULLES, M.D.,

The subject of properitoneal hernia has received but little attention in this country compared to that which has been devoted to it in Europe, and especially in Germany, where, under the influence of the careful and thorough study of Krönlein, it is now well understood; so that this form of hernia has there been a number of times recognized during the life of the patient, and successfully treated, by taxis or by operation, whereas, until Krönlein devoted his attention to it, its history had been one of uninterrupted error and disaster.

Krönlein's teachings in regard to this form of hernia have not yet been fully adopted—indeed, they seem to be scarcely known—in this country, or in Great Britain, so I have taken the opportunity afforded by a recent personal observation of a case to make it the starting-point for a presentation of the subject of properitoneal hernia as it is now understood.

The case I refer to is the following: Mr. S., aged fifty-six years, had suffered with hernia ever since he was a small boy, and perhaps since his birth. For many years he wore a truss, which became old and useless. A number of times his hernia had become painful, and had required considerable effort for its reduction. On September 6, 1886, after a natural movement of the bowels about midday, he found his hernia irreducible. Dr. John H. Musser was called to see him, and failing to effect complete reduction, even when the patient was etherized, called me to assist him. On examination about 9 P.M., I found the tumor different from anything I had ever before seen in a hernia. It was a hard, tense swelling, about as large as a fist, longer than broad, and lying above Poupart's ligament. It extended from near the symphysis pubis to near the anterior superior spine of the right ilium. The surface was marked by a slight furrow parallel to Poupart's ligament. (The illustration shows the appearance of the parts.) On pressure over the abdominal wall the hernia could be partly grasped in the hand, and it felt as if it was largely within the abdominal cavity. It was dull on percussion, and quite tender. The right side of the scrotum was empty and atrophied, the testicle being felt above the scrotum, in the inguinal canal, and flattened against the bottom of the hernia. The left side of the scrotum was normal, and contained a normal testicle.

A new attempt at reduction, under ether, failed, and the patient was ordered cold applications (pouring on of ether) and opium. He was more comfortable the next morning, September 7th. At this time, owing to some uncertainty about the previous history, and on account of the apparent presence of considerable fluid in the tumor, and of the absence of definite signs of strangulation, I had a suspicion that the case might be one of encysted hydrocele of the spermatic cord, partly within the abdomen. I therefore introduced an exploring needle, which evacuated some serum and moved about freely in what seemed to be a large cavity. I then introduced a small trocar and canula, but this only evacuated about four fluid ounces of bloody serum, while the upper and outer part of the tumor remained tense and elastic.

Prof. John Ashhurst was now called in consultation, and advised an exploratory operation—to be made a complete herniotomy in case the tumor was a hernia, as he thought it was. The operation was then performed with his assistance. His opinion proved correct, and with much difficulty the seat of strangulation was found and divided, and the intestine—a mass about as large as a small fist—was returned to the abdominal cavity. The sac was large, the intestine was dark but glistening, although it was somewhat roughened by recent deposits of lymph. It was necessary to divide two constrictions, one at the external ring, and one higher up and deeper in the abdomen. The incision in the sac was closed with catgut, and the incision in the skin with silver wire and black silk sutures. A

strand of catgut was left in as a drain, and the wound was dressed with lint soaked in a sublimate solution and with a pad of sublimate jute. The subsequent treatment consisted in the use of opium by the rectum, and small quantities of whiskey and water by the mouth. For forty-eight hours the patient had no pain worth mentioning, and no rise of temperature above 99⅘°, while his pulse fell from 140 beats in the minute immediately after the operation to 96 beats. His belly became slowly distended, and he had frequent attacks of hiccough.

On September 9th, fifty hours after the operation, his temperature was 99°, his pulse 96, his respiration unimpeded, his skin moist, his tongue moist and clean, his intelligence clear; he had no pain, his wound was dry and looked well, and there was not a single unfavorable symptom except the moderate tympany. His whiskey was now increased to three fluid-drachms every hour, and he was given a little hot beef-tea every half hour. In the evening his pulse was 96, and his temperature 98⅘°. The night was passed with some restlessness, and, for the first time since the operation, he passed some flatus. On September 10th, extract of hyoscyamus, half a grain, and assafœtida, five grains, were given hourly, to get rid of the tympany. He was also given some milk punch. In the evening he was manifestly failing; mustard was applied to his chest, and hot water and whiskey was given hourly. His heart-beat became feeble, and his respiration much oppressed. At 3 A.M. of September 11th I was called, and found his breathing so labored that I performed paracentesis of the intestine with an aspirator-needle, and evacuated considerable gas and about six fluid-ounces of grumous fluid, such as had come up from his stomach before. He had not vomited at any time, but at intervals part of the fluids taken into his stomach came up into his throat without effort and was spit out. As the tympany increased, the pressure seemed to squeeze up part of the contents of his stomach. This had a peculiar, mawkish odor, but no fecal characteristics. The paracentesis relieved the patient decidedly. His abdomen became relaxed, his breathing became easy and gentle, and his heart acted a little better. The issue was not changed, however, for he gradually sank, and died quietly at 7.30 A.M., about ninety hours after the operation.

Autopsy.—The autopsy was made by Dr. W. E. Hughes, in the presence of Dr. Musser and myself. The operation wound was thoroughly agglutinated and uniting, without any evidence of local irritation, although in the sac of the hernia two small pockets were found, each containing a little very thick pus. In the abdominal cavity there was no effusion. The stomach was large and dilated. The bowels were congested and pretty generally—but not firmly—agglutinated with recent lymph. The point of puncture in the intestine for paracentesis was patulous, but no fluid or gas had escaped into the peritoneal cavity. The portion of intestine lying next to the wound was in good condition, and showed no sign of inflammation. In the left iliac fossa a mass of small intestine, about the size of a fist, was found deeply congested and quite firmly bound together with lymph, and near it was the atrophied and distorted right testicle.

The history of this case illustrates a number of interesting points: the importance of early operation for incarcerated hernia; the advisability of operating, even if there be some uncertainty in the diagnosis; the fact that peritonitis may progress without any signs of inflammatory action except tympany, if that can be called such a sign; the difficulty of combating the progress of the tympany; and the deceptive character of an appearance of doing well for several days after operation.

But the most interesting feature of the case is the fact that it was, in my opinion, one of that rare form of hernia to which Krönlein has given the name of "properitoneal hernia."

This form of hernia is not accurately described in any of our American, or of the English, works on surgery, so far as I know. I will cite what I have been able to gather on this subject from the works of Fellows of this Academy.

The late Professor S. D. Gross, in his *Surgery*, sixth edition, vol. ii. p. 540, says: "There is a peculiar form of inguinal hernia, accompanied by an undescended testicle, in which the tumor extends uncommonly far outward and upward toward the crest of the ilium." And he mentions an interesting case, under his charge, in which such a hernia, of only five years' standing, extended from the symphysis pubis to the anterior superior spinous process of the ilium, and hung down over Poupart's ligament nearly as far as the upper third of the thigh. In this case the testicle occupied a very unusual position, namely, the outer side of the hernial protrusion, between the internal ring and the anterior superior spinous process of the ilium.

Professor Agnew, in his *Surgery*, first edition, vol. i. p. 471, speaks of the occasional presence of diverticula, generally in connection with congenital hernia extending backward beneath the iliac fascia into the iliac fossa, or inward into the loose tissue in front of the bladder, or upward between the integuments and the external oblique muscle, constituting what are termed "interstitial or interparietal" hernia. And, on p. 483, he says that an undescended testicle will sometimes force a rupture out toward the spinous process of the ilium, even down over Poupart's ligament upon the thigh. "This," he says, "forms the *intraparietal hernia* of some writers." And he mentions, on page 484, a case of the kind upon which he operated.

Professor Ashhurst, in his *Surgery*, third edition, p. 815, speaks of a form of hernia called "inguinocrural" by Holthouse, which is suddenly developed, and which, owing to some obstruction—as by an undescended testicle—protrudes along the folds of the groin; and of other forms in which prolongations of the sac (vaginal process) extend in various directions *within* the abdominal walls, constituting the *interparietal* or intermuscular herniæ of English authors, the "hernies en bissac" of French surgeons, and the inguino-properitoneal hernia of Krönlein. On page 825, he speaks of the complication of crural hernia with an additional sac between the peritoneum and the abdominal wall, in the cellular

tissue of the pelvis and side of the bladder. This form of hernia is termed "cruro-properitoneal" by Krönlein.

From these quotations it will be seen that the occurrence of such hernias as have been called "properitoneal" by Krönlein has not been overlooked by the Fellows of this Academy. But Krönlein's work in elaborating the subject entitles him to special recognition. Some confusion has doubtless taken place in naming their hernias, as is evidenced by the variety of terms proposed for them. It may be admitted that there are cases for which the term "intraparietal" or "intermuscular" would be more accurate than Krönlein's term, "properitoneal," but the terms "interstitial" and "interparietal" do not seem to me to be well chosen. The term "properitoneal," while not fully descriptive, may, I think, be accepted as convenient, and employed to describe hernias occupying unusual positions within the abdominal or pelvic wall in front of the peritoneum, lest an attempt to improve upon it should result in greater confusion than already exists, although as Sonnenburg has suggested "praeperitoneal" would be a more accurate term. The term "intermuscular" is a good one for a hernia between the layers of the abdominal muscles, and Küster has recently[1] proposed completing the nomenclature of these irregular hernias by adding the term "hernia inguino-superficialis," to designate hernias which lie outside the muscles, covered only by the skin and superficial fascia. These hernias he divides further into:

1. Hernia inguino-superficialis abdominalis,
2. Hernia inguino-superficialis cruralis,
3. Hernia inguino-superficialis perinealis.

as they occupy respectively the region of the lower abdomen, the thigh, or the perineum.

The adoption of these terms may contribute to accuracy in describing peculiar hernias; and it seems to me that it would be rational to speak of properitoneal, intermuscular, and superficial hernias as constituting three distinct and clearly defined classes. For the present we are concerned with the first of these classes, namely, hernia properitonealis.

The first paper by Krönlein, on this form of hernia, was published in 1876, when he was assistant to Professor Langenbeck.[2] In this paper Krönlein described a case of a man, fifty-four years old, who came under Langenbeck's care in 1875. The history corresponds in many particulars to that of the case under my own care described above. The man was within two years of the same age, but had a congenital right inguinal hernia, with an undescended testicle. He had worn a truss for twenty-seven years, and the hernia had recently escaped from its control and become incarcerated. The tumor occupied the right groin, and the testicle could be felt at the bottom of the swelling. On taxis the mass was thought to be reduced, but signs of strangulation recurred, and Langenbeck suspected reduction *en masse*, with internal strangulation. He then cut down upon the tumor through the abdominal wall the next day, opening what he supposed to be the abdominal cavity. He resected the intestine, which was gangrenous, replaced it, and sewed up the wound. The next day the patient died in delirium (alcoholic). The autopsy disclosed the fact that the operation had opened only a small sac in the inguinal canal and scrotum, and a large diverticulum between the transversalis fascia and the abdominal peritoneum, a properitoneal sac, in which the hernial mass was still contained.

The explanation of this case offered by Krönlein is that the patient had had a congenital inguino-scrotal hernia, which, when held up by a truss, had pushed its way up between the peritoneum and the transversalis fascia. Some new bowel came down into the inguino-scrotal sac, and the contents of the diverticulum became strangulated. The later protrusion was replaced by the taxis, the older became gangrenous, and, when operated upon, was left in its sac, which was mistaken for the abdominal cavity.

Streubel,[1] in 1864, published a paper in which he collected fourteen cases of apparent reduction of hernia, in which the hernia was wholly or partly in a diverticulum of the peritoneum. Krönlein has found other similar cases recorded by Dittel,[2] Bär,[3] Fieber,[4] Mosetig,[5] and E. Richter.[6] And Froriep[7] recorded, in 1846, a case so similar to that described by Krönlein that the latter very appropriately reproduces the description *in extenso*.

In Langenbeck's (Krönlein's) case the seat of strangulation was the opening into the properitoneal sac; in the majority of other recorded cases Krönlein thinks it was in the common opening into this and into the original sac in the inguino-scrotal region. It has never been found in the opening into the latter alone. All the cases recorded up to this time had ended fatally, and it seems that in not one had the nature of the hernia been recognized before death.

A similar complication in femoral hernia Krönlein proposes to call "hernia cruro-properitonealis."

The mechanism of properitoneal hernia is explained by Streubel as follows: When the neck of the sac has become contracted, pressure upon the contents drives the firm cicatrix of the neck up and presses out a lateral diverticulum under the muscles and above the peritoneum. This result may be favored by the action of an imperfect truss, or it may be caused solely by the obstruction of an undescended testicle. Bär and Richter attribute the formation of a properitoneal sac to the existence of a congenital or acquired anomaly of the parietal

peritoneum. In cases in which the testicle is found in the inguino-scrotal part of the sac, the diverticulum is supposed to have been associated with a congenital inguinal hernia.

The occurrence of such diverticula is not very rare, being mentioned by such authors as Rokitansky,[1] W. Gruber,[2] Linhart,[3] Hartung,[4] and Bär.[5]

In 1880, Krönlein published a second paper on this subject,[6] in which he collected 9 cases in addition to the 14 collected by Streubel, in 1864. In these 9 cases, as in the 14, the diagnosis was made only after the death of the patient, and no attempt at relieving the obstruction by taxis or by herniotomy was successful. In addition to these, Krönlein here reports a case of reducible hernia properitonealis, in a man twenty-two years old, which came under his observation in 1879. He also gives an abstract of the reports of all the cases thus far recorded—so far as he knew them—a total of 24 cases, as follows:

1. Fieber.[7] Man, thirty-two years old; left incarcerated scrotal hernia: herniotomy, death, and autopsy, at which an unsuspected properitoneal hernial sac was found on the *right* side.

2. Krönlein. Man, twenty-two years old. The case of reducible properitoneal hernia just mentioned.

3. Parise.[8] Man, thirty-four years old; incarcerated inguinal hernia (the side not mentioned); in which herniotomy was performed unsuccessfully, and the intestine was found in the properitoneal sac at the autopsy.

4. Cock.[9] Man, thirty-five years old; left incarcerated inguinal hernia; in which herniotomy was unsuccessfully performed, and the intestine was found in the properitoneal sac at the autopsy.

5. Textor.[10] Man, twenty five years old; right incarcerated inguinal hernia: herniotomy, death; autopsy, at which some intestine was found in the inguinal canal, and more in a pocket between the peritoneum and the bladder. In the operation the epigastric artery was divided.

6. Hilton.[11] Man, twenty-four years old; left incarcerated inguinal hernia; herniotomy, death; intestines found at autopsy in a sac lying on the iliacus muscle.

7. Birkett.[12] Man, thirty-six years old; right incarcerated scrotal hernia; supposed reduction, death; autopsy, intestine found in a sac within belly wall extending up toward the crista ilii.

8. Froriep.[13] Man, twenty-eight years old; internal strangulation, no tumor: no operation, death; autopsy, strangulated intestine found in open process in vaginalis, and in sac between transversalis fascia and peritoneum.

9. Dittel.[1] Man, nineteen years old; incarcerated inguinal hernia (side not stated): herniotomy, death; autopsy; two diverticula were found lying upon (over?) the transversalis fascia.

10. Langenbeck.[2] (Recorded by Krönlein.) Man, fifty-four years old; right incarcerated inguinal hernia; herniotomy, resection of gangrenous bowel, death; intestine found in properitoneal sac, which had been mistaken for the abdominal cavity.

11. Hernu.[3] Man, forty years old; right scrotal hernia: herniotomy, resection of omentum, no intestine in sac, death; autopsy, gangrenous intestine in a sac between bladder and pubic bone.

12. Cooper,[4] Sir Astley. Man, fifty-eight years old; right incarcerated scrotal hernia: reposition, continued symptoms of strangulation, herniotomy, sac empty, death; autopsy, gangrenous intestine in a sac behind transversalis fascia and going downward toward femoral ring, scrotal sac empty.

13. Janzer.[5] Man, twenty-four years old; reducible right scrotal hernia: internal strangulation, no operation, death; autopsy, some omentum in inguinal canal, a dark coil of strangulated small intestine in a sac behind the pelvic fascia.

14. Lehman.[6] Man, forty-five years old, reducible right inguinal hernia, strangulation, herniotomy, sac empty, death; autopsy, gangrenous intestine in a properitoneal sac behind the transversalis fascia.

15. Fieber.[7] Man, twenty-four years old; right incarcerated inguinal hernia: herniotomy, death; autopsy, inguinal sac empty, suppurating omentum found in a sac passing into the pelvis and resting upon the obturator membrane.

16. Von Wahl.[8] Man, thirty-eight years old; left incarcerated scrotal hernia: herniotomy, resection of gangrenous intestine, partial reduction, death; autopsy, inguinal canal empty, sutured intestine found in properitoneal sac passing upward and backward, muscles much atrophied.

17. Bär.[9] Man, fifty-two years old; right incarcerated scrotal (?) hernia: herniotomy, *no sac in scrotum*, small sac in inguinal canal replaced, death; autopsy, a foot and a half of strangulated small intestine in a sac between the bladder and the pubic bone.

18. Arnaud.[10] Man, sixty-eight years old; incarcerated inguinal hernia (side not stated): herniotomy, death; autopsy, dark intestine in a diverticulum of the sac in front of the peritoneum above the pubic bone.

19. Pelletan.[1] Man, forty years old; incarcerated left inguinal hernia: herniotomy, reposition, strangulation continued, death; autopsy, the bowels had been replaced, not in the abdominal cavity, but in a sac behind the pubic bone.

20. Cock.[2] Man, sixty-four years old; incarcerated left scrotal hernia: reposition, internal herniotomy, death; autopsy, sac between iliac fascia and peritoneum containing intestine and omentum.

21. Streubel.[3] Man, seventy-three years old; double reducible inguinal hernia: no tumor on right side, internal strangulation, no operation, death; autopsy, reducible hernia on left side, on right side empty inguinal sac, diverticulum between transversalis fascia and bladder, containing four inches of black intestine.

22. E. Richter.[4] Man, fifty-four years old: left inguinal hernia: apparent reduction by taxis, symptoms of strangulation continued, herniotomy, death; autopsy, coil of strangulated intestine found in a diverticulum of peritoneum extending from the internal inguinal ring toward the bladder.

23. Péan.[5] Woman, sixty-five years old the only female in the list); incarcerated left inguinal hernia: internal herniotomy, bowel apparently reduced, death; autopsy, bowel found to have been reduced into a sac between the iliac fascia and the peritoneum.

24. Tissier. To these Krönlein adds a case of cruro-properitoneal hernia in a woman thirty years old, reported by Tissier to the Anatomical Society of Paris, May, 1834.

I have been able to add to these statistics the following cases:

25. Neuber.[6] Man; strangulated inguino-properitoneal hernia in the right side, in which, in June, 1880, he opened the sac, removed part of the omentum, found an opening into the diverticulum above Poupart's ligament, stretched and tore it with the finger, reduced its contained omentum and bowel, tore the membrane wide open, excised the lower sac, closed the neck and the opening of the lower sac with a continuous catgut suture, put in an absorbable drain, and closed the wound and dressed it. The patient recovered without any trouble, and in less than four weeks was dismissed with a truss.

This is the first case in which such a hernia has been treated successfully by operation.

26. Krönlein.[7] Man; successful operation for a right strangulated properitoneal inguinal hernia, in January, 1881. The incision was carried from the anterior superior spine of the ilium, above Poupart's ligament, to the external ring. The testicle lay at the bottom of the hernia, and was removed. Part of the properitoneal sac was also removed, part being too adherent to the parietal peritoneum to be safely excised. The opening into the abdominal cavity was closed with catgut, and the transversalis fascia also. The insertion of a long drain, which was brought out of a counter-opening at the bottom of the right side of the scrotum, and closure of the external wound with silk sutures, completed the operation. The patient recovered without any interruption.

27. Santesson, of Stockholm, in 1858, saw a case of incarcerated inguino-properitoneal hernia which was discovered at the autopsy after an unsuccessful herniotomy.[1]

28. Rossander, operating for an incarcerated femoral hernia, found that it was of the cruro properitoneal variety, modified his operation accordingly, and his patient (a man) recovered.[2]

29. Trendelenberg.[3] Man, eighteen years old; strangulated right inguino-scrotal hernia: taxis unsuccessful, herniotomy, extension of incision, laparotomy through linea alba, reduction, closure of wounds, recovery. The patient had never worn a truss, never made attempts to restore his hernia, or even known that he had one.

30. Baron. (December, 1884.) Woman, sixty-eight years old; left incarcerated femoral hernia: herniotomy, division of crural ring, bowel returned; a second sac as large as a fist within the abdominal wall discovered, its opening drawn down(?), divided, reduction of bowel, wound closed, recovery.

31. Baron.[4] Man, (?) years old, incarcerated right inguinal hernia (February 26, 1886), as large as a walnut, with a swelling as large as two palms beneath the abdominal wall. Diagnosis of properitoneal hernia. Operation. Small inguinal sac, and properitoneal sac as large as two fists, containing forty centimetres of intestine; division of upper opening, reduction of bowel, suture of opening with catgut, drainage tube inserted, closure of wound, recovery.

32. Tansini.[5] Woman, fifty years old; incarcerated right crural hernia: herniotomy, resection of gangrenous intestine, continued signs of strangulation, death in four days. Autopsy: the intestine was found in a sac between the parietal peritoneum and the transversalis fascia, extending toward the true pelvis. As signs of such a complication, Tansini enumerates: 1, continuation of congestion of the bowel; 2, difficulty in replacing the bowel; and 3, the continuation of symptoms of strangulation.

33. Dulles. Man, fifty-six years old; incarcerated right inguinal hernia: undescended testicle, taxis, herniotomy, death, autopsy. (Case described above.)

In considering these statistics the following points are worthy of notice. The great majority of the patients were males (29 males to 4 females); the

The majority of patients were in middle life. In 16 cases the hernia was on the right side, and in 9 on the left. In almost all of the cases the hernia was congenital, and in many it was accompanied by an undescended testicle. In only six of the cases was the nature of the hernia diagnosticated during the life of the patient, and all of these patients were saved, one without operation and five after operation. In twenty-seven cases the diagnosis was erroneous, and all of these patients lost their lives.

This last is the most important point of all, and justifies an effort to call attention anew to this peculiar form of hernia; for it appears that until Krönlein made it the subject of study, and urged it upon the notice of the surgical world, its history had been one of unbroken disaster, and that since he did this, properitoneal hernia has become as amenable to surgical treatment as any other form of hernia.

I strongly suspect that a more thorough study of the statistics of hernia in general, and especially of a large number of accounts of cases published under equivocal titles would disclose the fact that there are many more cases of properitoneal hernia on record than have been included in this paper. A considerable number have doubtless been recorded in this country, and some of the whole number may have been cured by taxis, or by operations stated to have been very difficult, although their exact nature was not understood. It may, indeed, be inferred that one of the cases I have mentioned above (that of Baron, No. 30) the diagnosis was not clearly understood by the operator. Nevertheless, the fact remains that Krönlein's work has contributed to a very great improvement in the prospects of patients with properitoneal hernia, and it cannot be a waste of labor to endeavor to spread the knowledge of it in this country.

LEAD POISONING FROM AN UNUSUAL SOURCE.

BY EDWIN H. BIDWELL, M.D.,
OF VINELAND, N. J.

A FEW months ago I was consulted by a middle-aged farmer who complained of having suffered for a week or more with pain in the abdomen, constant, but rather worse at night, and sometimes increasing to almost a colic. Along with this, there were loss of appetite, *malaise*, and obstinate constipation. Not considering the case of much moment, I carelessly treated him "in the dark," with one remedy and another, for about ten days, without any appreciable change for better or worse.

Then it was suggested to me that the duration, now over two weeks, and the obstinacy of the abdominal symptoms indicated lead poisoning. No blue line upon the gums was detected, though it is not impossible that it was present. The urine was not examined. All the sources of lead poisoning then known to me, or that I could think of, were carefully investigated.

The patient, formerly an officer in the British army, and a very intelligent man with a considerable smattering of chemistry, gave valuable help in the search, and it did not seem that the cause of the lead poisoning, if such it was, could escape us. But no possible source of absorption of lead could be discovered. Nevertheless, it was determined to make a therapeutic test, and a short course of sulphate of magnesia, followed by iodide of potassium, cleared up the symptoms, and established the diagnosis.

The case was then set down as one of the unexplainable ones so frequently occurring in a young man's practice, and remained in that list until a week or so after the cure had been effected, when my patient called upon me to say that he had solved our puzzle. He makes domestic wine for his own consumption, and having some that had "gone wrong" he had distilled it together with the lees from his wine barrels. For the worm of his improvised still he had used a coil of lead pipe. When the use of lead in this way occurred to his mind, he remembered, for the first time, noticing in the last run of his "high-wine" or brandy, which was the first to be used for his daily "grog," a slightly sweetish taste.

Evidently some of his wine had undergone the acetic fermentation, and the acetic acid, being less volatile than alcohol, had distilled only at the last of the process, when, trickling down through the lead pipe, it had taken up and carried with it the poison as sugar of lead.

The fact that that portion of the distillate which had the peculiar sweetish taste had been consumed when the antidotes were finally given, no doubt contributed not a little to the prompt success of the treatment.

There have been reported in England recently quite a number of cases of lead poisoning by home-made wine, the fruit acids having acted upon the glaze of earthenware vessels used for fermenting. Such cases cannot be of frequent occurrence in this country, for here, or at least in that portion of the United States with which I am familiar, the fermentation of wine is almost invariably carried on in wooden receptacles.

My case shows a possible danger, also, in distilled spirits. But the danger here is, I judge, still less, for the possibility of contamination by lead is probably confined solely to the product of amateur distillers, and they, owing to the vigilance of Uncle Sam's revenue officials, are few in number, and their output not widely distributed. Still it may be worth while to put the case upon record as an illustration of an unusually obscure cause of a not uncommon ailment.

MEDICAL PROGRESS.

TERMINATION AND TREATMENT OF EXTRAUTERINE [illegible] follows on this subject: Whatever be the anatomical peculiarities of a case of extrauterine pregnancy it must terminate in the rupture or retention of the fœtal cyst. Rupture, which is exceptional in abdominal pregnancies, is the rule in tubal pregnancies, and often occurs at the second or fourth month. Occurring abruptly, it produces death by hemorrhage, peritonitis, strangulation, or septicæmia. Recovery can occur when the rupture occurs during the first weeks; early rupture produces the symptoms of periuterine hæmatocele, and the diagnosis cannot be made positively without an exploratory incision.

In exceptional cases recovery may occur in cases further advanced, the fœtus dying and undergoing absorption, or living until viable. A retained fœtus may become encysted as a foreign body, and undergo calcareous degeneration; this degeneration presents great varieties.

It is well, with Barnes, to advise patients in whom encystment has resulted favorably to avoid subsequent pregnancies, as the retained cyst may become the occasion of dangerous accidents: when new pregnancies occur they may give rise to inflammation and suppuration in the cyst, and peritonitis follow.

Spontaneous evacuation of ruptured cysts occurs through the intestines, the abdominal wall, the vagina, and the bladder.

Treatment varies with the stage of fœtal development.

In early months, before the rupture of the cyst, it should be removed by laparotomy; the fœtus may sometimes be removed per vaginam.

When the cyst ruptures immediate gastrotomy is the only treatment; in Lawson Tait's hands 21 of 21 patients so treated recovered.

In the last months of pregnancy, when the child lives, laparotomy will save the mother from the dangers which threaten; when the child is dead, the expectant plan should be followed, and laparotomy done only as dangers arise which necessitate it.

When the fœtal cyst is only partially opened, the intervention must vary with the case.

In summing up, the author considers laparotomy indicated in the first months of extrauterine pregnancy, and at the rupture of the sac; in the later months of pregnancy, when the child lives (with special care against placental hemorrhage), and when the child has been dead for some time.

Elytrotomy is preferred when the fœtus is fixed in the pelvis, when the placenta is not lying between the cyst and the vaginal wall.—*Revue de Chirurgie*, November 1[illegible].

SURGICAL ANTISEPSIS IN THE BULGARIAN WAR.—In one of the last numbers of the *Archives de Médecine Militaire*, M. AUDET gives a brief surgical history of the Serbo-Bulgarian War. Of three thousand wounded men carried to Belgrade Maydl reported fifty-one deaths, twenty-two of which were due to tetanus, leaving a direct surgical mortality of less than one per cent. Iodoform dressings were used, and there was not a single case of erysipelas, notwithstanding that the sanitary and moral surroundings of the wounded were very bad. Of two hundred wounded, Schmidt reported only three deaths; there were four cases of traumatic erysipelas, but none of gangrene or of pyæmia. Dressings of iodoform and corrosive sublimate were used. At Sophia the wounded were received in a pronounced septic condition, but the same favorable results were obtained by antisepsis. Notwithstanding the lack of care on the battlefield, of one hundred and thirty-six cases of injuries, many of which were wounds of bones or articulations, reported by Dr. Blum, there was no case of pyæmia or erysipelas. Iodoform gauze was used in these cases. Similar favorable results were reported by other surgeons in the field, and a comparison of these statistics with those of like injuries a few years ago leaves little room to doubt the value of antisepsis and cleanliness in the treatment of wounds.

IODOFORM IN PHTHISIS.—HUCHARD combines iodoform with creasote in the treatment of phthisis as follows:

R.—Iodoform,
Creasote,
Pulv. benzoin.
[illegible]
Sig.—Two to four pills daily.
— [illegible]

THE DIETETIC TREATMENT OF ECZEMA.—PROFESSOR SCHWENINGER (*Charité-Annalen*, xi.; *Monatshft. f. prakt. Dermat.*, Nov. 1886, p. 521) believes in dieting eczematous patients, but not after any hard-and-fast general dietary laws. Each patient must be treated according to his case, and at first be put upon as simple a diet as possible. When this basis is reached, the patient's taste is to be consulted and his diet made more varied, care being taken to avoid anything that is known to disagree with him. Sometimes it is advisable to have a patient increase the number of meals in a day, while decreasing the quantity of each one. Some patients do best on solid food alone, leaving out tea, coffee, and the like. Sometimes the best results are obtained by having the patient eat of only one sort of food at a meal—whatever he fancies. In many cases of chronic eczema a liberal supply of water, or rather of fluid, is useful, and this not taken at once, but often in small quantities. Up to three quarts of fluid may be taken in this way. The addition of salt to the dietary is also useful.

HYSTEROGENIC ZONES ON MUCOUS SURFACES.—Attacks of a spasmodic or of a lethargic nature in hysterical patients can often, as is well known, be excited by touching or pressing upon certain spots or zones on the surface of the body. These external "hysterogenic" zones were examined and described by M. Gaube, and later by M. Blanc Fontenille. Quite recently, too, M. Lichtwitz, who had been asked by M. Pitres to examine a hysterical patient laryngoscopically, observed that a severe convulsive attack was produced by touching the epiglottis, and subsequently by examining the mucous membranes of half a dozen hysterical patients, he has been able to show that hysterogenic zones exist there as well as on the external surface. In all the six cases the

nasal fossæ were the seat of spasmogenic zones, which were bilateral except in one instance, in which touching the nasal mucous membrane on one side produced a hypnotic attack. In four cases either spasmogenic or lethargogenic zones were found in the laryngeal mucous membrane, the posterior wall of the pharynx presenting one instance of each kind. The mucous membrane of the gums, the conjunctivæ, and the external auditory meati also furnished "zones." In some of the cases the sensitiveness was obliterated by cocaine, so that necessary therapeutic applications could be made; in other cases the use of cocaine did not succeed. In one case, in which the leg was in a plaster bandage, where a violent attack might have proved serious, a convulsion, which was accidentally induced by touching the mucous membrane, was arrested immediately by a friend whom the patient had brought with her, who was acquainted with her external spasmo-inhibitory zones.—*Lancet*, December 25, 1886.

MYRTOL has been recently studied by DR. LINARIX, who obtains it from the leaves of the myrtle; its distillation gives a liquid of characteristic fragrance, of less density than water, staining paper but the stain evaporating perfectly. Its taste is hot, a little acrid, followed by a sensation of coolness. Myrtol is an excellent disinfectant and antiseptic. It is unirritating to the intact skin; upon denuded surfaces it produces a not unpleasant sensation of moderate heat which is of brief duration. It stimulates the digestive functions; it is sedative to the nervous system, and is eliminated by the kidneys and respiratory organs. In cases of chronic bronchitis with muco-purulent expectoration, in catarrhal asthma and dilatation of the bronchi it has been successfully given in doses of two and a half grains five or six times daily. It effect upon digestion has been stimulating, and no unpleasant symptoms have attended its use.—*L'Abeille Médicale*, December 20, 1886.

THE EFFECT OF RETAINED MEMBRANES ON THE PUERPERAL STATE.—DR. FISCHER, of Professor Slavianski's clinic, writing in a recent number of the *Vrach*, gives the result of a number of observations made for the purpose of testing the commonly received view that portions of membrane retained in the uterus after the expulsion of the placenta are liable to produce serious consequences—as hemorrhage and especially the so-called auto-infection or septicæmia—and that, therefore, it is of the utmost importance that they should be removed by the hand or by intrauterine injections. This view is supported by the authority of Winkel, Dohrn, Ahlfeld, and others; while Olshausen, Credé, Weiss, and Landau consider that there is little harm in the retention of even considerable portions of the chorion. Dr. Fischer's observations extended over 682 labors, in each of which he carefully examined the after-birth. In forty-two of these cases (*i. e.*, 6.2 per cent.) a portion of the chorion was retained. Credé's method of manipulating the fundus uteri gave the best results regarding the percentage of retention. In primiparæ retention was nearly twice as frequent as in multiparæ, the percentage being 9.1 and 4.9 respectively. Some effect appeared to be exerted by the time at which the rupture of the amnion took place, which, when either too early or too late, seemed to predispose to retention. Premature deliveries also were rather more frequently followed by retention than those at term. As a rule, the retained chorion came away in the course of from four to six days, generally in several small portions, sometimes, however, in fragments of considerable size, and in one case, where three-quarters of the chorion had been retained, it was passed entire on the fifth day without having caused either hemorrhage or sepsis. Amongst the forty-two cases hemorrhage occurred only four times, and was always easily arrested either by hot irrigation or by ergot and manipulation of the uterus. When, however, we learn that out of the forty-two cases manual extraction of the fœtus was required seven times, and that a considerable loss of blood occurred during the third stage eleven times, four cases of slight post-partum hemorrhage do not appear at all excessive. With regard to pyrexia, in twenty cases, or 47.6 per cent., there was none; in twelve, or 28.6 per cent., the thermometer, which was always used thrice a day, once registered a rise above normal; and in ten, or 24.8 per cent., there was more or less pyrexia. In order to compare these with cases in general, Dr. Fischer gives the results of similar observations made on all the cases he has attended for the last two years. These show that there was no pyrexia in 58 per cent., that the temperature was only once above normal in 17.6 per cent., and that there was pyrexia in 24.4 per cent.; so that the ratio of appreciable pyrexia was about the same in the cases in which retention occurred as in ordinary cases. A slight amount of endometritis occurred in three out of the forty-two cases. Dr. Fischer concludes from his observations that there is no ground for supposing that retention of fragments of membrane gives rise to "auto-infection," and considers that the commonly received view is fraught with danger, inasmuch as it tempts the accoucheur, when sepsis occurs, to throw the blame, not on himself, as he ought to do, but on some fancied auto-infective process, and this probably prevents his being as particular as he should be in employing antiseptic methods in the management of the labors he has to attend.

COCAINE IN LABOR.—DR. HERTZHORNE recommends (*Lancet*) the use of a compound of six parts of cocaine, twenty-four of vaseline, and twenty of glycerine, to be applied to the parturient canal during the second stage of labor for the purpose of producing anæsthesia of the parts, and so vastly lessening the pain incident to that stage.

FORMULÆ APPLICABLE TO THE TREATMENT OF VARIOUS FORMS OF GOUTY DIATHESIS.—In the treatment of gout of long standing, without complications, VIGIER employs the following to prevent relapses:

℞.—Lithii carbonat. . . . . ℥ijss.
Extr. gentian. . . . . ℈iv.—M.
Ft. pil. c. in num.
Sig.—One pill after each meal.

When gout is complicated with nephritic colic, it is well to replace the carbonate with the benzoate of lithium as follows:

℞.—Lithii benzoat. . . . . ℥ijss.
Extr. gentian. . . . . ℈vss.—M.
Ft. pil. c. in num.
Sig.—One pill morning and evening.

In chronic gout, with calcareous concretions about the joints, iodide of sodium or potassium should be associated with lithium as follows:

R [illegible]
Sodii iodid. sicc. . . . ʒijss.
Extr. gentian.,
[illegible]
Ft. pil. c. in num.
Keep in tightly corked bottle.
Sig.—One pill after each meal.

Also the following:

R.—Lithii carbonat.,
[illegible]
Gum. acac. pulv. . . . ʒss.
Extr. gentian. . . . . ℈iijss.—M.
Ft. pil. c. in num.
Sig.—One pill after each meal.

Iodide of sodium being deliquescent, the powdered licorice, indispensable in the former, is not needed in [illegible]
Chirurgie, December 31, 1886.

ACTION OF DRUGS IN ALBUMINURIA.—An interesting communication on this subject was read in the Section of Therapeutics at the Brighton meeting of the British Medical Association by Dr. Robert Saundby. He pointed out the difficulty of foretelling what action drugs might possess on the renal processes in genuine albuminuria. The number of drugs with which he experimented was very large. The following are his chief conclusions: Alkalies used in the form of diluents—such as a quart of bitartrate of potash imperial (one ounce and a half to a pint), daily—gave distinctly favorable results in cases of chronic persistent and copious albuminuria. He has employed, also, citrate of lithia, bicarbonate of potash, ammonic benzoate, and bicarbonate of soda, and includes them in the favorable opinion. The beneficial effect was not due to the formation of alkali-albumen, for Esbach's fluid, which was the method employed, precipitates that form of albumen. Tannate of soda, or rather an ounce mixture of tannic acid and bicarbonate of soda, of each ten grains, with fifteen minims of glycerine, also gave good results. In one case the albuminuria was diminished nearly one-half. Nitroglycerine and fuchsin appeared to have no good effect. Digitalis and other heart tonics—caffeine, strophantus, sulphate of sparteine, iron salts, acetate, sulphate, and perchloride—increase the amount of albumen passed. Apocynum was not found to have any diuretic action in drachm doses of the tincture, and it increased the albumen in two cases. Turpentine had no beneficial effect, though hæmaturia followed its employment in one minim doses. Doses of the 1000th of a grain of bichloride of mercury were also inoperative. —*Lancet*, December 25, 1886.

UTERINE CANCER IN PREGNANCY AND PARTURITION. —BAR, of Paris, has found that cancer of the cervix is greatly influenced by pregnancy; the pain and hemorrhage, its growth and extension to neighboring organs, and the cachexia caused by cancer are all so greatly increased that death may occur before the end of pregnancy.

Cancer often produces abortion.

The presence of a neoplasm in the cervix uteri, and the abnormal resistance of the tissues, with the uterine inertia, are a frequent cause for the prolongation of labor in these conditions; this delay may continue fifteen or eighteen hours, and cause the death of mother and child. Premature labor generally occurs very readily.

The diagnosis of pregnancy is made difficult in many cases by cancer. The prognosis is very grave, and the death of the mother is, sooner or later, inevitable. Regarding treatment Bar counsels palliation, and deprecates abortion and premature birth, which give no certain benefit to the mother.

Amputation of the uterine neck induces labor in only a portion of the cases so treated; the author had but one death after the operation, and no cures; a palliation of distressing symptoms was observed in a large number of cases, but parturition was complicated by the presence of cicatricial tissue; vaginal or abdominal hysterectomy is not commended.

At parturition, when the cervix is not dilated and the child is living, it is best to wait, and when grave dangers threaten perform Cæsarean section. If the child is dead it is still best to wait, the justifiable interferences being Cæsarean section or embryotomy with forcible extraction.

When dilatation has begun, but is incomplete, and the child lives, the use of Barnes's dilators and the excision of the tumor, if it is not too large, are recommended. If labor must be rapidly terminated the Cæsarean section must be made in case of uterine rupture or very large tumor; when dilatation can be effected by incisions the forceps or the ablation of the tumor may permit the birth of a living child. If the child is dead, the performance of embryotomy is indicated.

Premature labor will be generally easy, as the small size of the child will permit its extraction by the natural channels.—*Revue de Chirurgie*, November 10, 1886.

TREATMENT OF ECZEMATOUS OTITIS. — MIOT, in moist eczema, orders the injection, twice daily, of a portion of the following:

Sodii bicarb. . . . . ʒiv.
Aquæ picis . . . . . Oij.

Morning and evening an application of the following by means of a bandage:

Acid. pyrogallic. . . . . ʒijss.
Vaselinæ . . . . . ʒxij.
Sulph. sublim. . . . . ʒijss.
Alcohol. camphorat. . . . . ʒss.
Chloral hydrat. . . . . gr. xv.

Two or three times weekly the free application of this [illegible]

Tinct. iodin. . . . . ʒss.
[illegible]
Aquæ [illegible] . . . . . ʒijss.
Potass. iodid. . . . . gr. viij.
Tinct. opii (Sydenham) . . . ʒss.

In dry eczema, the author recommends the following pomade once or twice daily:

Hydrarg. sulphat. flav. . . . gr. iv.
Vaselinæ . . . . . ʒiv.

[illegible] December 24, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding registered letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 22, 1887.

THE TREATMENT OF SYPHILIS.

THE great obstacle to unanimity in regard to the proper treatment of syphilis, is the fact that a number of recognized authorities differ in regard to its nature. It is well known that the great majority of those who have made a special study of this disease are dualists, and would separate clinically all cases in which subsequent manifestations warrant the opinion that a venereal sore was a syphilitic sore, from those in which no such manifestations arise. Others, among whom Mr. Jonathan Hutchinson is conspicuously eminent, still use a nomenclature which is founded upon a not unusual similarity of appearance in different venereal sores, and which ignores their different results. As we share entirely the scientific opinions indicated by the term dualism, we feel regret that the theoretical views of unicists should so often seem to obscure the practical results which might be gained from a more exact, and, we believe, more correct way of studying the clinical history of syphilis.

The question whether or not mercury is to be regarded as a true antidote to syphilis cannot, we think, be decided so long as unicists claim that it is so because later evidences of syphilis do not follow when mercury is given in cases which they call syphilitic and which dualists deny to be so. The latest evidence of this fact is furnished in a most sensible and temperate paper by DRYSDALE, in the *British Medical Journal*. The opinions of Solly, Erichsen, Hutchinson, and Henry Lee, that mercury may effect an early cure of syphilis are cited, and are met by the opposite opinions of Lancereaux, Diday, and Fournier. To these we may add that of Sigmund, who, before his death, came to the conclusion that the part played by mercury as an antidote to syphilis is not very important, and attributed more and more importance to the effect of general tonic and strengthening measures. Some years ago, Tasenson published a valuable book on the treatment of syphilis in which he assigned the first place to tonic treatment, and placed treatment by so-called specifics in a decidedly subordinate position. The opinion in this country seems to be very much that entertained by Sigmund toward the end of his career, and a reason for it may be found in the demonstration by Keyes that mercury in moderate doses is a decided hæmic reconstructive.

It may be asserted, without fear of contradiction, that mercury administered in cases that are indubitably syphilitic, in the view of dualists, cannot be expected to cut short the disease. It cannot be denied that, when properly used, it exerts a beneficial influence upon the course of the disease, and that it is probably the drug most universally suitable to its treatment; but we cannot understand how anyone of large experience and of a critical mind can assert that it is an antidote to syphilis. Even when it is most judiciously used late lesions may show that it certainly has not acted as an antidote, and the fact that in a number of cases in which it is used no such accidents occur is offset by the fact that in many cases they would not occur at any rate. This is so true that there is a constantly growing conviction that syphilis is a self-limiting disease, which, under favorable conditions, tends to a spontaneous cure. This conviction was plainly expressed by Sigmund, and it must be given its due weight in discussing the claims of any special method of treating this disease.

CORROSIVE SUBLIMATE IN TYPHOID FEVER.

AT the present time, when the specific fevers are believed to be due to the presence of microörganisms, it is not surprising that various plans of antiseptic treatment are advanced. The trials and suggestions are in every way praiseworthy, as it is quite possible that we are on the eve of important therapeutic advances in this direction. The problem would be readily solved could we deal with the vital fluids as we can with solutions in the laboratory, but the great difficulty is to find remedies which will neutralize or destroy the specific agents, without, at the same time, acting injuriously upon the tissues of the body.

Typhoid fever seems, in many respects, to be the most suitable disease in which to test antiseptic plans of treatment, and various remedies have been used with, so far, doubtful success. Carbolic acid and iodine, of which we heard so much a few years ago, seem no longer in favor. In the remarkable revival of the use of mercury in acute diseases it is natural that certain of its preparations, which have

powerful antiseptic properties, should come into vogue, and we find that in Germany corrosive sublimate is being extensively tried.

[illegible], 1885, reported forty cases, without a death, under the use of sublimate, and claimed that it rapidly reduced the fever, and improved the general condition. At the Hamburg General Hospital, Glaser has tested the method very fully, and published his observations in *Deutsches Archiv f. klin. Med.*, Bd. xl., the general result being expressed in the title of the communication. *The sublimate treatment appears to be without influence in typhoid.* He denies that in safe doses there can be any question of parasiticide action, as the degree of dilution in the fluids of the body is too great. Twenty-three cases were treated, of which five died. In only four cases did the temperature sink to normal before the nineteenth day; in six cases from the twentieth to the twenty-third, and in eight cases defervescence was still later. The state of the tongue was not affected, the general condition of the patients not materially bettered, and neither the duration of the disease nor the tendency to relapse in any way influenced. The paper is accompanied by elaborate tables, illustrating the daily progress of the cases.

ACTINOMYCOSIS HOMINIS.

WE have already referred in THE NEWS of October 16, 1886, to Israel's important monograph on the clinical features of actinomycosis. Since the attention of the profession has been directed to the subject, the reports of cases are becoming more frequent, and there have been several new cases in the western States, where the disease has been known for some years in cattle. In the *American Journal of the Medical Sciences* for January, 1887, SKERRITT reports a very remarkable case, in which the fungus invaded the liver through the lung. The patient, a man, aged twenty-eight years, had been failing in health for three months, with loss of flesh and strength, and three weeks before admission to the hospital had acute pain under the right costal cartilages. There was irregular fever, with signs of moderate effusion into the left pleura, but on aspiration only a small amount of fluid was obtained. During the second month in the hospital the features of the case suggested phthisis, but the copious sputa gave no indications. These symptoms subsided, and the lung seemed to clear except at the base in front and behind. Subsequently rigors and colliquative sweats became marked, and the patient died of exhaustion sixteen weeks after admission. Fibroid induration was found at the base of the right lung, with intimate adhesion to the diaphragm, immediately below which, in the substance of the right lobe, was a yellowish-white mass, three inches in diameter, composed of a fibrous stroma, in the loculi of which were the characteristic actinomyces tufts. The case affords a striking illustration of the migration of the fungi, for, no doubt, the lung was first involved, then the pleura, and, subsequently, the liver, through the diaphragm.

THE UNIVERSITY OF WESTMINSTER.

THE London schools of medicine have, at last, the prospect of the establishment of an institution at which their pupils can obtain a degree in medicine. The great majority of students have now to be content with the license of the College of Physicians, the membership of the College of Surgeons, or the license of the Society of Apothecaries, as the requirements for graduation at the London University are so stringent that only a small number of the best men can possibly conform to them. At the Scotch schools, on the other hand, the M.D. is, as with us, the usual conclusion of a course in medicine. In Great Britain the possession of a university degree counts for much in practice, and the London students have naturally felt aggrieved, and the schools have been seriously handicapped in the competition with the Scotch universities. It is proposed that the Colleges of Physicians and Surgeons should unite, and obtain from Parliament the power to confer a degree after examinations the equivalent of those which the student has now to pass for the diploma of the College of Physicians or the College of Surgeons. It is suggested that the new examining body be known as the University of Westminster. There will be difficulties in carrying out the scheme, particularly if the two Royal Colleges persist in denying to the Society of Apothecaries the right of participation in the new institution.

THE progress of our knowledge with reference to the etiology of infectious diseases has been so rapid during the past three or four years that it is difficult for one who does not devote himself especially to bacteriological studies to keep pace with it. This is largely due to the fact that many of the monographs in which the results of extended experimental researches are given, are published in journals which, in this country at least, are scarcely known, and are only to be found in the library of the Surgeon-General's Office. We have an excellent annual *résumé* of the work of the year in this department of knowledge in the *Jahresbericht* of Baumgarten, first published in 1855. But so great is the interest in this fundamental branch of medical science that, in Germany at least, the want has been felt of a periodical devoted exclusively to bacteriology, which might give at frequent intervals a synopsis of all important papers published in the various lan-

guages of Europe. As Germany has taken the lead in this field of investigation, it is not surprising that the first announcement of a weekly journal of bacteriology should come from that country, and, indeed, it is doubtful whether such an enterprise could be sustained elsewhere.

The new journal to which we have reference is published in Jena by Gustav Fischer, and is under the editorial management of Dr. O. Uhlworm, of Cassel, assisted by Prof. Leuckart, of Leipzig, and Dr. Löffler, of Berlin. These names suffice to establish, in advance the character of the journal, which will be known as the *Centralblatt für Bacteriologie und Parazitenkunde*. The names of many well-known workers in this field of investigation, from the various countries of Europe, appear as co-laborers, and through these *Mitarbeiters* the editors hope to receive promptly copies of all papers of value published in the various countries in which bacteriological studies are pursued, for the purpose of publishing abstracts or editorial notices. Dr. G. M. Sternberg has been requested to act as "co-laborer" in this country, and will forward to the editors reprints of papers of value, in which original researches are recorded. The authors of such papers in the United States or Canada are requested to send duplicate copies, when practicable, to Dr. Sternberg, Johns Hopkins University, Baltimore, Md.

IN THE MEDICAL NEWS of December 4, 1886, attention was called to certain dangers arising from the use of water-gas. The justification of this warning is to be found in the recent events in Troy, N. Y. On the 5th instant twelve persons in four different houses were alarmingly prostrated by an escape of this gas. On the 17th instant thirty persons were similarly affected; of these three have died, and several are still seriously ill. The gas is made by the Lowe water-gas process, is absolutely odorless, and contains nearly thirty per cent. of carbonic oxide. Pending further investigation its manufacture has been prohibited by the Troy Board of Health.

We shall present to our readers at an early day a full report of the medical history of these cases.

THE Surgeon-General of the Army, in his annual report to the Secretary of War, recommends that authority be granted by Congress for the printing of the catalogue of the Army Medical Museum, which, with proper illustrations, it is calculated, would make three large volumes, and would be of great value to the profession and to the Museum.

A LAW which shall make the disinfection of rags compulsory before they find their way into the hands of the workers in our paper mills is urgently called for by the outbreaks of infectious diseases which from time to time occur among such persons. The village of Ivybridge, which has several times suffered from epidemics of smallpox conveyed by this means, was, according to the *British Medical Journal*, the scene of a fresh outbreak on December 11th. Three girls, similarly employed, were attacked on the same day, and the local board of the village has decided to erect a building to be used as a hospital for such cases. We believe that rags are frequently disinfected by the owners of paper mills, but until it becomes a compulsory enactment the danger will continue.

THE Library of the Surgeon-General's Office contained at the close of the last fiscal year, June 30, 1886:

	Volumes.
Medical journals	24,115
Medical society transactions	3,532
Bound theses	1,385
Bound pamphlets	1,331
Other medical books	46,368
Total	76,732
Unbound medical theses	42,212
Unbound medical pamphlets	64,419
Total	106,631

THE SOCIETY OF MEDICAL OFFICERS OF HEALTH, in reply to a communication from the London police authorities, have recommended the adoption of the following method of disinfection of cabs: The cushion and as much of the internal fittings as are movable should be taken out of the cab and put in a disinfecting oven, where such is available; if there is no disinfecting chamber, the cushions, after having been taken out, if movable, well beaten and dusted, should be replaced, putting them on end so as to expose both surfaces to the action of the chlorine gas which is subsequently used. All exposed woodwork on the inside of the cab should be washed with carbolic acid soap; and carbolized oil should be smeared over the metal work, with the view of disinfecting it, and protecting it from the action of the chlorine. Chlorine gas should be evolved inside the cab, and the cab shut up and kept exposed to the fumes for one hour.

J. J. CHISOLM, M.D., of Baltimore, Md., has been appointed President of the Section of Ophthalmology of the Ninth International Medical Congress, in the place of Dr. E. Williams, who was compelled to resign on account of ill health. Judson B. Andrews, M.D., Superintendent of the Hospital for the Insane, Buffalo, N. Y., has been appointed to the office of President of the Section of Psycho-

logical Medicine and Nervous Diseases, made vacant by the recent death of Dr. John P. Gray.

IN Great Britain, during the past year, 5210 new books, or new editions, were published; of these 755 were novels, and 616 were books on theology. The total number of medical and surgical works was but 114, and of new editions 57; this is, of course, exclusive of medical periodicals and serials in volumes, which number altogether 291. Small as the number of medical books appears in comparison with that of works of fiction or theology, it is relatively enormous in comparison with new books on law and jurisprudence, of which there were but 18, and only 16 new editions during the year.

THE 51st Annual Meeting of the Medical Society of the State of New York will be held at Albany on February 1st, 2d, and 3d, under the presidency of Dr. William S. Ely, of Rochester. The preliminary programme, just issued, gives promise of a most in-

THE first course of the Middleton Goldsmith lectures, will be given by Dr. M. Allen Starr at the hall of the College of Physicians and Surgeons, of New York, on the evenings of January 25th and 28th. The subject is multiple neuritis, and its relations to peripheral neuroses. The lectures were recently founded by Dr. Middleton Goldsmith, of Rutland, Vermont, and are given under the auspices of the New York Pathological Society.

THE publication of the third medical volume, the last of the series comprising the *Medical and Surgical History of the War*, has been delayed by the pressure of current work at the Government Printing Office. The completed manuscript was ready for the press in February last, but scarcely a fourth of it is yet in type.

DR. DEAVER, last week, removed the right kidney from a patient at the German Hospital in this city. One week after the operation the case was doing well.

MEASLES seems to be greatly on the increase in New York. Cases are now reported to the Board of Health at the rate of 100 a day, and the indications are that the total for the past week will be over 700, an increase of over 200 on the figures for the preceding week. There are many cases in public and private schools and charitable institutions, and it is probable that there is not an institution in the city in which children are collected in which the disease is not more or less prevalent.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, December 22, 1886.

[illegible]

DR. SANDS presented a patient eleven years old, whom he had treated for a cicatricial stricture of the œsophagus more than three years previously, and whose case he had made the subject of a paper read before the Society, January 22, 1884. (See THE MEDICAL NEWS, February 9, 1884.) As she was now on a visit to New York he availed himself of the privilege of showing her to the members, and of demonstrating the passage of large bougies through the œsophagus at the site of the former stricture which, when the patient first came under his notice, was so small that only instruments of filiform size could be introduced. After a number of operations of internal œsophagotomy had been performed, however, the child left New York in November, 1883, entirely relieved of dysphagia, and into the stomach a bougie, No. 40 F, could be readily passed. When her case was related before the Society some doubt was naturally felt regarding the duration of the improvement, which, it was believed, would be only temporary. Dr. Sands was therefore interested in stating certain facts connected with her past and present condition. After the cutting operations were discontinued, the patency of the œsophagus was tested with bougies at intervals of increasing length, until May, 1886.

Between that date and October, 1886, a period of seventeen months, no instrument was used; and when, at the end of that time, the calibre of the œsophagus was examined, bougie No. 40 could be readily passed beyond the site of the former stricture. Within the past week Dr. Sands had introduced a bougie of that size, and he demonstrated before the Society the easy passage of a bougie No. 38 F. No. 40 was not tried, because the patient did not wish to have so large an instrument employed, as it caused discomfort when passing behind the cricoid cartilage.

Dr. Sands remarked that he attributed the long absence of recontraction to the shortness of the stricture, as well as to its complete division. He hoped that the cure would prove permanent. The patient's health had for a long time past been excellent, and no difficulty was experienced in swallowing solid food.

DR. SANDS presented a patient from whom he had

REMOVED A NASO-PHARYNGEAL POLYPUS BY MEANS OF THE GALVANIC ECRASEUR,

and read the following account of the case, which had been copied from the records of Roosevelt Hospital:

Henry Robinson, aged eighteen, Irish, single, laborer, admitted October 26, 1886, family history negative. Had always had good health. Gave no history of phthisis, Bright's disease, or rheumatism. For ten or twelve years patient had had a thick, difficult enunciation, but this trouble had made no noticeable progress. His other symptoms were all of recent date, beginning with a cold caught ten months ago. After this he had much difficulty in breathing through the nose; eight months ago

the patient had a slight hemorrhage from the nose which was easily stopped; but four months afterward a more severe bleeding began, and lasted a week, occurring three or four times a day. Since then, talking and breathing had been much worse.

On admission, patient was a large, strong-looking young man, but appeared rather anæmic. Examination of the pharynx showed a round, smooth mass pendant from the posterior nares and projecting into the upper part of the pharynx. It was slightly visible beneath the free border of the soft palate when the mouth was well opened. It could be easily felt by the finger, and was found to be of a rather soft and compressible character. The finger could be passed without difficulty in front of and behind it, showing that no adhesion existed and that the probable origin was from in front of the foramen lacerum medium. Examination through the anterior nares showed that only the left side was wider. The growth was not seen from this direction. Patient had no discharge from the nose, and was chiefly inconvenienced by the obstruction to breathing. Urine: Amber colored, alkaline, 1.033; five per cent. albumen; phosphates; ammonium urates.

Treatment: *28th.* Ordered Blaud's pills (gr. vj) ij t. i. d. *30th.* Ordered compressed oxygen by inhalation. *Nov. 3.* A wire was easily passed through the left nostril into the mouth and made to surround the new growth.

6th. Cocaine anæsthesia; operation. A copper wire was introduced through the left nostril and brought out through the mouth. To this the end of a platinum loop was connected and passed back again. The platinum being brought out of the nostril, care was taken that these wires did not cross. The loop was then adjusted about the polypus and drawn up tightly, and its free ends passed through the handle of a galvano-cautery, which, in turn, was pressed as far as possible through the left nostril toward the posterior nares. The connections were then established and a fair current of electricity was passed over the platinum wire, heating it to a red heat. Just before the current was applied, a strong silk suture was passed through the bottom of the polypus by a curved needle, so that traction might be made on the tumor from below, and that it might be prevented from slipping out of reach when the pedicle should be divided.

The operation was rather slow (six minutes being required), and during this time there was a good deal of bleeding, and the patient seemed to suffer pain. At last the pedicle was divided, and the tumor drawn out of the mouth. The bleeding then ceased and did not recur. The pain also did not continue. The polypus was half the size of an egg (circ. 1½ in. x 1¼ in. in diameter). The pedicle had been very evenly removed close to the body of the tumor.

7th. Patient had no bleeding after the operation, and no pain.

9th. Patient had no bleeding at all, but has a slight nasal catarrh. Discharged cured.

Microscopical examination by Dr. Delafield showed it to be a polypoid fibroma.

His object in bringing the patient before the Society was mainly to emphasize the fact that very few cases of nasal pharyngeal polypus are suitable for treatment with the galvano-cautery. The method, which dated back to the time of Mitteldorf and his followers, has been practised often enough to prove its value; but, as most nasal pharyngeal polypi are attached to the skull by a broad band, and cannot be embraced by a loop of wire, this safe and easy method of operation is inapplicable. There was no difficulty in handling the pedicle.

DR. PETERS said he had operated on several naso-pharyngeal polypi, but had never seen one with a narrow stem like that presented by Dr. Sands.

DR. LANGE presented a specimen removed from a patient suffering from cancer of the tongue; the history being as follows:

EXTIRPATION OF TONGUE, FLOOR OF MOUTH, AND SUBMAXILLA FOR CANCER.

A very vigorous and otherwise well-preserved and healthy gentleman consulted me for a cancerous disease which had taken its origin from a fold between the margin of the tongue and the floor of the mouth on the right side, and though not presenting, to a great extent, superficial ulceration, had infiltrated the soft parts toward the base of the tongue and in the suprahyoid region. An extensive glandular infiltration on the right side likewise existed, and some enlarged glands were found in the left submaxillary region. About four months previously pharyngeal symptoms had appeared, and lately the sufferings had become very severe. The main source of trouble to the patient was a constant, abundant salivation, which had been hardly influenced by the division of the lingual nerve by another surgeon some time before.

The patient wanted to be relieved at all hazards, and though the operation had been refused by a most competent surgeon of this city, I decided to do it for the following consideration:

Supposing it to be possible to form, after the very extensive loss of tissue to be expected in consequence of the operation, a new floor of the mouth by a plastic operation, so that healthy mucous membranes were turned against the oral cavity, and the wounded surface excluded, we might avert the principal danger after these operations, those of repair and "Schluck pneumonie." The part of the horizontal ramus of the jaw adjacent to the tumor had to come away, and the operation was done in the following way: After preliminary tracheotomy, the contents of the submaxillary fossa on the left side were removed first, and the lingual and external maxillary arteries tied. A corresponding incision was then made on the opposite side and the infiltrated portion of tissue laid bare. The right half of the hyoid bone had to be resected also. Then after cutting through the lower lips corresponding to the dental fossæ the soft parts, including the periosteum, were removed from the external surface of the horizontal ramus of the jaw, and that portion of bone removed. I then had very free access to the diseased parts, and after tying the lingual and external maxillary arteries, the most of diseased tissue down to the epiglottis and hyoid bone could be rapidly removed with only very little loss of blood. So far, the patient had borne the operation very well. He had suffered no excessive loss of blood, his pulse was good, respiration very quiet, the trachea acting very well.

The mucous membrane of the left half of the floor of the mouth had been purposely preserved, and I now

tried to unite the edge of [illegible] the [illegible] of the external surface of the [illegible] to the base of the tongue, the parts of the right side not yielding sufficiently on account of the ascending portion of the jaw still being present. This, therefore, had to be removed, and it seemed to me as if the unavoidable manipulations connected with this act of the operation, and probably the irritation at the inferior maxillary nerve caused by it, contributed to a rather sudden deterioration of the pulse and appearance of the patient. After the artificial floor of the mouth had been formed, the external wounds were left open and loosely packed with gauze. I intended to do on the second or third day a secondary suture. The tracheal tampon tube was replaced by the usual tracheotomy tube. The patient rallied well after the operation. He had a fair pulse of about 112, became conscious, and expressed his satisfaction at the operation being over.

When I came to the hospital on the following day, the man had died rather suddenly. The temperature had risen to 107° and after a short period of unconsciousness he had expired. After the operation I had placed a soft rubber catheter through his nostril into the upper jaw to avoid deglutition into the trachea. An autopsy was refused, and I am at a loss to say what was the real cause of death. It may have been a very acute pneumonia or nephritis, which I have observed in a few cases after protracted ether narcosis. Possibly the disintegration, by ether, of a large portion of the red blood-corpuscles may have set free so much blood ferment as to account for the sudden change.

The operation as done in this case lasted certainly too long, but I think it would be much shortened by first tying the external carotid on one or both sides. The perpetual cutting through bleeding vessels which have to be tied is, indeed, the main source of the dangerous prolongation.

In spite of the unfavorable result in this case I should follow the above plan in a similar case, while, on the other hand, I freely admit that such a risky undertaking in regard to the best results that can be achieved, can only be justified by the miserable outlook which the patient will have if nothing is done. In a further case I should also carefully keep the tracheal tamponade for some time after the operation. It struck me during the operation that by sewing up the posterior part of the floor of the mouth the epiglottis was somewhat drawn forward and the entrance to the larynx widely opened.

DR. LANGE also presented the specimen from a case of [illegible]

His patient was a married woman about fifty-five years of age, in whom a far-progressed cancerous disease was detected shortly before the operation on account of obstinate hemorrhage. The operation was done after Morton's method, and was attended with a great deal of difficulty on account of the broad inversion of the supra-vaginal tissues in Douglas's wall as well as toward the parametria, both of which, especially on the right side, were already somewhat affected. Coarse silk was used for all the preliminary ligations. Though some of the offensive contents of the uterine cavity, which, in spite of free irrigation, could not thoroughly be cleansed, had escaped during the operation into Douglas's space, no peritonitis followed, the after-treatment being the open antiseptic treatment with iodoform gauze used against the wound surface. The patient made a good and comparatively rapid recovery, so that six weeks after operation she could be discharged with only a small granulating surface at the end of the vagina. Though the prognosis with regard to the probable early recurrence of the disease is not flattering, still the patient has been benefited by the operation. She has picked up in strength and her life, at all events, will be prolonged and made more tolerable. The cancerous affection includes the whole cervix and the infiltration reached somewhat above the internal orifice. The ovaries and tubes were left. Thiersch's spindle with handle proved to be a very useful instrument in this case also.

DR. H. B. SANDS read a paper on the

USE AND ABUSE OF PASSIVE MOTION.

(See page 85.)

DR. YALE remarked that there were so many interesting topics raised in Dr. Sands's paper it would be difficult to discuss them fully, but the speaker considered the use of hot water in sprains of great value, gradually raising the temperature of the water as hot as it could be borne, and afterward applying compression. This he found would alleviate the pain in many cases where the injury did not involve the bony part. The cases he considered most likely to suffer ankylosis from enforced rest are those arising from gonorrhœal rheumatism, and similar pseudo-pyæmic affections, as in such patients ankylosis more or less severe occurs quite frequently. In the majority of cases of ankylosis he had found that after the adhesions had been broken up and the acute symptoms subsided, good motion is generally secured in the joint. But in those chronic cases of the kind alluded to he had often met with complete failure.

DR. BRIDDON said that the paper of Dr. Sands had thrown a ray of light on what the editor of the London *Lancet* had called a dark corner in the domain of surgery. The editorial referred to applied to papers published in that journal fifteen years ago by Dr. Wharton L. Hood, and subsequently issued in book form, under the title, "On Bone-setting (so-called) and its Relation to the Treatment of Joints Crippled by Injury, Rheumatism, Inflammation, etc.," a book from which he had culled much that was valuable and instructive. It was in return for services rendered to Mr. Hutton, the renowned bone-setter of Great Britain, that Dr. Hood was allowed to witness the procedures by which he certainly achieved many successes; in one portion of his book he refers to a communication made to him by Mr. Ponsonby in which the latter gentleman, in facetious but not flattering terms, refers to the treatment of a bad sprain by parboiling, and subsequently prolonged rest advised by two prominent surgeons and that was at last promptly cured by the manipulations of the "bone-setter." Dr. Peter Hood devised a treatment for sprained ankles that had given him more satisfaction than any other, strapping the whole foot and ankle with adhesive plasters and a firmly applied bandage arranged so as to prevent any stretching of the lacerated tendons, and changed every day.

Dr. Briddon desired to endorse the opinion of Dr.

Sands with reference to the treatment of firm, fibrous ankylosis by forcible movements. He had succeeded in restoring function to some disabled limbs by such means but had more often failed. In the early part of the present year a lady was placed under his charge with a knee badly damaged by rheumatic arthritis. It was flexed, the head of the tibia displaced backward, and the leg rotated. There was a scarcely perceptible movement, and the patella was immovably fixed to the condyles. We had her under the full influence of ether and arranged on a stout table with all the advantages to be obtained by using the leg as a lever. It required all the force we could bring to bear before we succeeded in flexing and extending the limb to our satisfaction and the reports of the rending adhesions were truly alarming. On the following day there was no local elevation of temperature, but the parts were so sensitive that she would not permit him to touch the limb until she was placed under the influence of ether. For a month he made daily movements under the anæsthesia and then finding the same conditions as those present the day after the operation, the same sensitiveness and inability on the part of the patient to move the joint, he gave up in despair, and to prevent the return to a faulty condition, he immobilized it extended. In regard to passive movements in cases of fracture in the vicinity of the joints, referring especially to those in the neighborhood of or involving the elbow, and including the epiphyseal separations of children, he would say that he would not treat such unless he was allowed to make easy passive movements; in the early part of his career he saw so many stiff joints where the parts were kept uninterruptedly at rest, that he had since insisted on early gentle movements which could be done without materially disturbing the fracture.

DR. GEORGE A. PETERS said that he was in the habit of keeping the patient in bed when suffering from a severe sprain, and treating the injured part with hot water and compression. The speaker remarked that eighteen months ago a case came under his observation involving the knee-joint. Having heard so much talk of massage, he put a masseur under his own observation and the result was very satisfactory. He had since tried it in other cases with good effect, and was inclined to think with favor of thoroughly applied massage. In those cases of false ankylosis of joints, and fractures in their neighborhood, it has long been his practice, as soon as their union is firm, to put the patient under an anæsthetic and rupture them by strong manipulation. He has never had cause to regret such treatment and believes it to be preferable to the slower methods of passive motion, which the patient is prone to neglect on account of the pain occasioned.

With regard to passive motion in joints implicated with fracture extending into them, it is his practice to remove the dressing say after the fourth or fifth day and resort to very gentle motion. This he continues every second day or so until he is satisfied with the results obtained. One advantage, at least, of such treatment is that the apposition of fragments is good and deformity less likely to result.

Fractures of the bones of the forearm near the wrist he has long treated with two short anterior and posterior splints, neither of them extending down upon the hand; these being secured in place, the arm is carried in a sling, the hand allowed to hang loosely and the patient directed to use the hand and fingers as much as possible during the entire treatment. By this method he has secured results which are entirely satisfactory.

DR. POORE said that he had seen some eight or ten fractures of the elbow-joint in which passive motion was made early; but in one case no motion was made until the parts were healed and the dressings removed finally; in this case the result was excellent also. In regard to ankylosis, either bony or fibrous, he has seen great disasters follow attempts at motion; from his own experience he believes much good could not be secured at the hip-joint from manipulation, and that when it occurs at the knee-joint much improvement cannot be obtained, especially after suppurative disease.

DR. ABBE remarked that he must express strong objections to any motion that excites pain. He considers that this should limit the amount of passive motion, further motion being liable to start up some inflammatory trouble. The speaker considered voluntary motion on the part of the patient much better; in the elbow and shoulder-joint the patient will generally do this; and in six months can almost always get rid of plastic adhesions resulting from fractures. As to faulty ankylosis of the knee-joint following gonorrhœal inflammation, he had observed an article published by Dr. Barwell, in the *Lancet*, in which resection of the bone was advised in preference to violent rupture in order to secure an improved position. The speaker quoted a case in which he had assisted Dr. Weir, occurring in a woman whose knee was flexed at more than a right angle; the adhesions were broken up, and after a reasonable time the patient was taught to make passive motion. She drew the foot backward and forward by an elaborate apparatus devised for this purpose, but at the end of a year she had not gained much, and had started up meanwhile some inflammatory action, which caused great anxiety.

DR. BULL considered Dr. Sands's remarks very opportune. Some think it necessary after fractures to make passive motion at a certain time, and frequently inflict pain in so doing, which the speaker considered unnecesary. He thought the idea of passive motion at the end of three weeks in fracture of the patella wrong, as, if there be a fracture needing freedom from motion, it is this fracture. In his practice for the last ten years he has not allowed motion until the eighth week. In one or two cases, where motion had not been regained at the end of the eighteenth week, passive motion had been made under ether, and the joint liberated. Dr. Bull had met an instance of the advantage of the "faith cure" in a patient who would not submit to the manipulation he proposed. This woman, who had had a fractured patella, believed in the faith cure, and visited a "shrine" in Hoboken; she was told to kneel down; she complied, and heard something snap, and she afterward had a good knee. In fracture of the elbow-joint the speaker had felt but little hesitation about abandoning the old tradition "that passive motion was necessary." But in fractures opening into the joint he had made passive motion two or three times a week, and at the end of the fourth week the patient was treated with manipulation of the joint; better results had been secured by this means. He had also directed the patients to apply a hot poultice to the joint

every night for two or three weeks, after commencing passive motion. Under this influence and their own manipulations stiffness soon disappeared. As time went on, the speaker was using less and less passive motion in his practice. He thought there should be some definite understanding on the point. He doubted if passive motion diminished stiffness permanently. In speaking of fracture of the wrist-joint Dr. Sands considered them a different class of cases, and in the average fracture, if kept at rest, the cure will not be attended with any stiffness; but he had always been in the habit of allowing the patient to move the wrist and fingers at the end of a week or ten days, and would advise this practice in order to prevent adhesions of the tendons. Dr. Bull remarked that Dr. Sands had referred to periarthritis in speaking of articular rheumatism of the shoulder-joint. In some few cases of laboring men he had forcibly ruptured the adhesions under ether and secured good results. In relation to passive motion in gonorrhœal ankylosis of the joints the results had not been satisfactory. In the treatment of sprains Dr. Sands had followed out the same method which the speaker considered the best. As to the use of hot water, he had not gained much from such applications, and would never use hot or cold water in the swelling of a fracture.

The President remarked that his views were much the same as those of other members of the Society. He would like, however, specifically to add his testimony against early resort to passive motion. It was his opinion that the stiffness of the knee following fracture of the thigh was due in part to a coincident sprain of the joint; only in the joints of the fingers did he think immobilization was liable to cause persistent rigidity; and he, therefore, had considered it necessary in treating the upper extremity to make passive motion of the fingers at an early date. In relation to fractures in the neighborhood of the joints, in which the joint was not injured he had no apprehension of ankylosis, but when the joint is directly involved in the fracture there is reason to fear it, as a consequence of the change in the shape of the surface. One argument in support of early passive motion is that exuberant callus may be thereby moulded and shaped so that it will less impair the motion of the joint. Dr. Stimson thought this was purely theoretical and incapable of proof. His opinion was, that the exuberant growth of bone seen in children is due to the stripping up or irritation of the periosteum; and the quieter the joint is kept and the more complete the reduction of the displacement, the less the irritation of the periosteum. His treatment in fracture is to leave the parts quiet for three or four weeks, inspecting them once or twice a week to make sure that the fracture remains reduced, and occasionally changing the angle at which the joint is held. When the splints are removed the joint is always more or less stiff but its motion usually increases rapidly. In hospital cases it is not easy to speak positively as to ultimate results, as it is difficult to follow them up.

Dr. Sands said he was somewhat surprised to find that his views concerning passive motion resembled so closely those of his colleagues, as he had come prepared to hear that their experience had led them to form on many points opposite opinions. He drew attention to the frequency of ankylosis after fracture of the elbow, compared with the occurrence of stiffness following fracture involving the hip, the knee, and the ankle; and he was unable to explain the difference except by assuming that the complicated and bony structure of the elbow often interfered with proper reduction. He urged close attention to this point in the early management of the fracture. To put off what ought to be done at once, and to endeavor to prevent stiffness by employing passive motion, is a common and unfortunate delusion.

Dr. Peters, in reply to the inquiry whether the sprains of which he had spoken were severe, said that two of them were. The results of treatment of many were, however, very satisfactory, recovery having followed at an earlier period than usual.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

[illegible]

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. H. A. Wilson reported, for Dr. John B. Roberts,

A CASE OF SUPRAPUBIC LITHOTOMY,

followed by death from perforating ulcer of the stomach. The case with which the suprapubic operation can be performed, due largely to the distention of the rectum and bladder by the fluid forced into them previous to making the first incision, was clearly demonstrated in this case. The facts that union of the bladder wound and early restoration of the functions of the bladder in regard to urination readily occur after the high operation for stone, and that wounding of the peritoneum is easily avoided, make this method of removing vesical calculi very satisfactory. The unfortunate death of the patient from disease of the stomach does not in any way vitiate the results of the operation; for, although the patient had not recovered sufficiently to be discharged from treatment, still the operation had effected the results which were sought.

The President presented

A SERIES OF THREE EPITHELIAL OR PSEUDO-MEMBRANOUS CASTS OF THE TONSILS AND PALATINE FOLDS FROM A CASE OF DIPHTHERIA.

The patient was an adult, and had exhibited no symptoms of a constitutional infection. The local disease was limited to the tonsils and palate; one tonsil became parenchymatously enlarged, and underwent suppuration. The abscess was opened twice. At present there is an additional abscess in the upper portion of the palate. There has been no complication in the case, except from difficulty in deglutition, so great that for forty-eight hours the patient had to be nourished mainly by the rectum. Two days ago there was brought to Dr. Cohen a thin sheet of false membrane, which was an accurate mould of the tonsil and palatine fold. Yesterday a similar mass of desquamation, having much the same shape, was brought; and this morning a third mould had been thrown off. The appearance of the second cast closely resembles a cast of the interior of the larynx and trachea, and could readily have been mistaken therefor had there been any laryngeal complication. Manipulation, however, demonstrates that it has sheathed the tonsil and one of the palatine folds.

The point to which particular attention is called is the physical resemblance of these patches to the desquamated epidermis in scarlatina.

CORRESPONDENCE.

ELECTRICITY IN THE TREATMENT OF COLD ABSCESSES.

To the Editor of THE MEDICAL NEWS,

SIR: In reading the editorial entitled "Injection of Ether and Iodoform into Cold Abscesses," recently published in your journal, it occurred to me that your readers might be interested in a phase of the subject little understood or discussed. I refer to the use of electricity in developing and curing cold abscesses. The subject was quite fully discussed by me in the *Medical Record*, September 21, 1878, in an article entitled "A New Method of Hastening the Suppuration of Acute and Strumous (Cold) Abscesses," and, so far as I know, was the first, and perhaps the last, contribution to literature upon that subject. It is simply referred to in our work on electricity; but since that time I have had a number of opportunities to verify the statements as originally made. Given a cold abscess, the persistent application of the faradic current is, according to my experience, quite sure to develop it, and render it fit for opening. The pus once evacuated, the cure soon becomes complete and permanent.

The activity of the suppurative process is influenced more or less by the physiological, chemical, and physical effects that are more especially within the province of galvanism, but it is the mechanical influence of the faradic current that most rapidly tends to hasten suppuration. It is a current of alternation, of to and fro motion, of constant closing and breaking. When it passes through the body, even when it produces no appreciable muscular contraction, it acts very much in the same way as gentle tapping, or pounding or rubbing on the tissues; and this gives passive exercise to all the deeper lying as well as the superficial tissues. We may believe that the molecules of the tissues are agitated by the passage of the current, as the particles of a bar of iron are moved by the influence of magnetization, or as bodies are expanded by heat. The numerous branch currents going to and fro act as so many shuttlecocks, keeping every atom in incessant disturbance. While it is in virtue in part of these phenomena that we obtain tonic and restorative effects in ordinarily vitalized tissue, we can readily understand how, when acting on parts where the destructive process has begun, they may act as excitants, and very materially accelerate the breaking down of tissue and the consequent formation of pus. In the cases of this kind that I have treated, the patients were not kept from their usual work during the application of the current, and only for a few days after the evacuation of the pus.

In one case an enlargement on the neck had existed for several years, which by surgeons, both here and abroad, had been diagnosticated as a "tumor." At one time the knife was suggested, and at another resolution by electrolysis. The patient coming under my care, a small trocar was introduced, and traces of pus found. Under daily application of the faradic current, continued through several weeks, the swelling greatly enlarged. I then made an incision, evacuating several ounces of pus. The wound healed quickly and kindly, and the so-called tumor, of course, rapidly disappeared.

A. D. ROCKWELL, M.D.

NEW YORK.

[1] Beard and Rockwell on Electricity, 5th ed., p. [illegible].

AGARICIN IN THE SWEATING OF PHTHISIS.

To the Editor of THE MEDICAL NEWS,

SIR: The article of Dr. Armistead Peter, in THE MEDICAL NEWS of January 8th, concerning the employment of agaric in the sweating of phthisis, reminds me that during my term of service at the Episcopal Hospital in 1885, I used *agaricin* extensively for this annoying symptom and with very satisfactory results. I prescribed it in doses of one-tenth grain with one grain of Dover powder, in pill, as recommended by Seifert, of Würzburg, who was, I believe, the first to use the drug.

Very respectfully,

FREDERICK P. HENRY, M.D.

PHILADELPHIA, Jan. 17, 1887.

AN ACCIDENT WITH ETHER.

To the Editor of THE MEDICAL NEWS,

SIR: In Dr. John H. Packard's article entitled "An Accident with the 'A.-C.-E.' Mixture," in THE MEDICAL NEWS of January 8, 1887, he quotes Reeve as saying that "Ether, in the human subject, may produce death as suddenly, as unexpectedly, and in the identical manner that chloroform does," and expresses his doubt as to the justice of Reeve's opinion, attributing fatal result in such cases to existing disease.

A case which occurred to me last May, and furnished me with an hour of anxiety never before suggested in twenty-four years' experience with ether—my preferred anæsthetic—may throw light on the possibility of death under ether.

The accident occurred to me while removing a small pyriform fibroid tumor from the cheek of a patient of Dr. E. P. Talley, of Moro, New Mexico. My patient was a Mexican, forty-five years old, tall, light, and active, weighing about one hundred and forty-five pounds. He could not bear odors of any sort—foul or agreeable, and he has had to avoid all alcoholic stimulants. I examined his heart and found it healthy and learned that he was not subject to attacks of faintness. He seemed very nervous and anxious, but desirous to be rid of his deformity. He took the last rites of his church over night and in the morning made his will, and in various ways discovered his peculiar nervous temperament. He was unable to eat any supper the preceding evening, and was told to eat no breakfast in the morning as the operation was fixed for 9 A.M.

Squibb's best ether was administered in a towel covered by a newspaper cone with its apex partially occluded with absorbent cotton. He took the ether readily, barely moving once or twice as if it were disagreeable, and in twenty minutes was wholly unconscious.

The tumor was easily removed within five minutes, and I was stanching the rather copious venous oozing when suddenly the oozing stopped, and at the same instant Dr. Talley exclaimed, "He has stopped breathing!" Heart and lungs had ceased their functions

simultaneously. The face was pale; pupils not noted. At once I drew the man to a level, dashed cold water in his face and compressed his chest by spells, but there was no reaction. He seemed dead.

Ordering his body well surrounded with hot bottles and stones and plenty of blankets, I instituted systematically Sylvester's method of artificial respiration, several strong men taking turns at it. At each compression of the chest a dismal toy-dog squeak occurred at the larynx. Hypodermatic injections of fluid extract of digitalis and tincture of belladonna were given several times. At the end of half an hour he rallied a minute and vomited a little, but at once relapsed. Several times I listened to the heart and barely detected a feeble pulsation at the rate of ten or fifteen to the minute. Slapping the precordial region with a wet towel caused a deep inspiration, but the effect was only transient. We were thirty miles from any electric apparatus or nitrite of amyl. Artificial respiration was continued for a full hour when we were rewarded by a rather abrupt restoration of both heart and lungs to fair activity.

I gave in all thirty minims of the digitalis and forty of the belladonna. Upon his recovery we had twenty-four hours of mild digitalis poisoning to watch. Having always associated inversion of the body with chloroform poisoning, I inadvertently omitted its use in this instance, although the head was promptly lowered to a level with the rest of the body. It was easy afterward to regret not having given atropine and whiskey before the operation, but the recollection of the excessive nervousness caused in a recent case by these preliminaries had temporarily prejudiced me against them.

After the artificial respiration had proceeded a short time the muscles of the chest, shoulders, and arms became so stiff that manipulation was very difficult—painfully simulating *rigor mortis*. I had used about three and a half ounces of ether.

I may say in closing that there was no struggling, no vomiting before the accident, no cyanosis, no abnormal variation in pulse or respiration. I have no doubt the man would have died had we been a very little less active in striving to revive him.

In another similar case—while not forgetting inversion—I should especially depend upon the application of warmth and artificial respiration.

NEWS ITEMS.

The College of Physicians of Philadelphia.—*The [illegible]* [illegible] ing upon the recent centennial celebration of the College, says: "Such festivities represent something more than mere self-congratulation at the completion of a century, or than the gratification of an instinct for generous hospitality. They represent for Philadelphia an acknowledgment of the many advantages which have accrued to the medical profession and to the public from the existence and the prosperity of the College; to the stranger, who was within her gates, they should represent the wisdom and importance of founding and fostering similar institutions elsewhere.

"A suitable building where physicians of rival medical schools, of different views and different modes of practice may meet and discuss the questions of the day face to face on neutral ground; where medical societies may convene in proper halls surrounded by books, by a museum, by portraits of distinguished worthies of previous generations—such a building is needed in all our large cities. It should be under the control of a corporation representing the energy and the liberal intelligence of the medical profession in the community, of a body of men actuated by the spirit as well as the letter of the motto, 'Non sibi sed toti.'

"Such a corporation would exercise needed authority and would be often appealed to by a perplexed public in questions of State, of preventive medicine, and might even succeed to some extent in realizing the last clause of the comprehensive list of objects given for the foundation of Philadelphia's College, namely: 'The cultivation of order and uniformity in the practice of medicine.' New York has such an institution in process of development in the Academy of Medicine; in Boston the Medical Library Association offers the possibility of a similar evolution; but the College of Physicians of Philadelphia in its past history, its present organization and equipment is *facile princeps*, if not alone, among such institutions as we have pictured and would like to see flourishing in our large cities, especially in such as are centres of medical thought and education."

The Massachusetts General Hospital.—We learn that the trustees have decided to build a new ward, to be devoted to abdominal surgery. The details of its arrangement have not yet all been decided upon, being left largely to the judgment of the surgical staff, but the general idea is that of an operating theatre with beds attached. The foundation will soon be laid.

The Medical Signers to the Declaration of Independence.—The statement in the recent address of the President of the College of Physicians of Philadelphia, that Rush "was the only physician whose name is on that energetic arraignment of the Crown" (the Declaration of Independence) should not pass unchallenged. Josiah Bartlett, of New Hampshire, and Lyman Hall, of Georgia, were successful practising physicians; Oliver Wolcott, of Connecticut, studied for the profession [illegible] Jan. 13, 1887.

Retirement of Professor Pajot.—On the 18th of December the pupils and friends of Prof. Pajot met to present his bust in bronze to the distinguished instructor on the occasion o his retirement and seventieth birthday. After Prof. Pajot had taken his farewell, Dr. Dolóris expressed the regrets of his pupils, and M. Peyron, Director of Public Assistance, conveyed the congratulations and regrets of the administration.

Mr. Stuart C. Cumberland, of Mind-reading Fame, gives a very frank and rational account of his doings, in the December issue of the *Nineteenth Century*. As a child, his perceptions were unusually keen. But his career as a mind-reader began only six years ago. His first attempt was entirely impromptu, but was as successful as any afterward. The gift was present; and future practice made it only quicker and more delicate, but not more certain. At first Mr. Cumberland frankly confesses he was apt to imagine himself supernaturally

endowed, but soon convinced himself that the whole thing is simply an ingenious and skilled interpretation of the unconscious movements of the subject. "Willing is either dragging or pushing," is the mind-reader's formula. "Distinct and intense apperception, fixed attention is incipient motion," is the psychologist's conclusion.

The account of Mr. Cumberland's experiences with the nobility and eminence of Europe is extremely readable; but some notice of his general conclusions will be of greater interest here. The best subjects are among active brain-workers, statesmen, scientists, etc., where concentration is easy and usual. Military men make excellent subjects; lawyers are dodgy and unsatisfactory; musicians cannot fix their attention on anything but music; artists are better subjects; clergymen are perfect in the drawing room but not in public; physicians are good subjects when they have no theory about thought-reading. Von Moltke was the best and M. Dumas the worst subject. Englishmen and Germans are, perhaps, the best races for subjects; while uncivilized races, such as Chinamen and Indians, are bad. Mr. Cumberland's opinion on thought-reading without contact is well worth quoting in full: "Some mystically inclined people claim to be able to read thoughts without contact. For my part, I have never yet seen experiments of this kind successfully performed, unless there had been opportunities for observing some phase of physical indication expressed by the subject, or unless the operator was enabled to gather information from suggestions unconsciously let fall by somebody around. I have on several occasions managed to accomplish tests without actual contact, but I have always been sufficiently near to my 'subject' to receive from him—and to act accordingly—any impressions that he physically might convey."

HYGIENE OF CHILDHOOD.—On the first of May, 1887, will be opened in Paris an Exposition of the Hygiene of Children. The chief of the Organization Committee is Dr. Chassaing.

The Exposition will be technical in character, and embrace all the agencies which apply in the rearing and hygiene of children until the twelfth year of life; it will remain open a month.

TRAINING OF NURSES IN JAPAN.—Arrangements have been made to organize a school of nursing in Kyoto, Japan, under the superintendence of Dr. Berry and Miss Linda Richards, an American lady, who has had large experience, not only in New York and Boston, but in several British and Continental hospitals. The schools, which are especially connected with Christian missionary effort, will give a course of training of about eighteen months' duration, including both theoretical teaching and practical work. A diploma in nursing will be awarded to those who prove themselves competent.

DEATH FROM SEWER-AIR.—An inquest was held at Liverpool, on the 8th inst., on the body of a youth who had been employed as apprentice to a plumber. The deceased had, in the previous week, been engaged in repairing some pipes connected with other pipes which led into a sewer. A good deal of gas came through the pipes, and the deceased complained of pain and sickness. He went home, feeling ill, and died in forty hours. The medical evidence was to the effect that death was due to the inhalation of sewer-air, and the jury returned a verdict in accordance with this testimony.

EUROPEAN MEDICINE AND PHARMACY.—In recent European travel of eight months duration, Dr. Squibb made the following observations upon foreign medicine and pharmacy:

"The pharmacies of European cities offer a striking contrast to those of this country. In England and Ireland they appear to be similar in character, but perceptibly less numerous. In Scotland they are less conspicuous and less numerous than in England, and in France the character and number are still further modified for the better. But it is in other European cities that the contrast becomes most marked. As a broad generalization it may be that in number they reach one-third of the number in this country, but probably not over one-fourth; but the contrast in character and appearance is still more remarkable than in number. Never near together they are commonly in prominent locations, and not uncommonly appear to occupy the whole of a small building. No show window nor colored bottles nor any other form of display. Windows of ordinary size and character, and used only to admit light, except that they may occasionally have one or two growing medicinal plants. No glaring nor large signs anywhere, but generally a small one over the entrance door with the name of the proprietor, and the word 'Apotheke.' Inside the door is a clean clear space occupied by a few chairs. Then a very simple counter without show cases, and without furniture, or with one or two scales of large size. Behind the counter and with their backs toward it are from one to four clerks, each with a prescription scale and measures, engaged in putting up prescriptions or orders. Beside these, the proprietor or his representative appears to be engaged in receiving those who enter, and in superintending the work of the clerks. As a general rule males who enter remove their hats as soon as the door is passed, and remain uncovered until they are served and go out. In many visits to such pharmacies very few verbal messages were noticed, almost all messengers bringing written orders or prescriptions, though they often received only a single article. The proprietor or disengaged clerk receives the order, and invites the bearer of it to sit down, and not once was a messenger seen to sit down without being invited. Often not a word was spoken until the order was supplied and presented, when the clerk would mention the price, or the messenger would ask for it, and, as a rule, conversation seemed to be avoided. The clerks were generally of mature age, intelligent looking, personally clean, and well, though very plainly dressed. The furniture and apparatus was clean and in good order, but clumsy, and there was a notable absence of gaudy, overgilt labels and ostentatious decoration of anything, everything being plain and substantial, even to ugliness and clumsiness. Not a patent medicine card, nor any proprietary article in sight, and no perfumery, fancy goods, soaps, cigars, wines, waters, nor soda fountain in sight. In short, the whole pervading tone was of quiet, earnest, and accurate work of a high order, carefully done, and this tone gave a dignity and an honorable rank to the

whole place. The writer commonly made an errand of buying a few grammes each of ether, chloroform, and carbolic acid, articles the quality of which could be fairly judged by their sensible properties, and such purchases gave access to the pharmacies, and opportunity to observe the work. The first of these orders was given in Copenhagen verbally through a clumsy mixture of bad French and worse Latin. The clerk, a very young man, very respectfully suggested English, in an excellent specimen of that tongue, and never after was the writer again caught in the same way, and this led to the observation that, with very few exceptions, English was spoken and understood in the pharmacies of Europe.

The articles bought were often of very good quality, and never of bad quality, and were uniformly dispensed quickly and neatly, but never elegantly.

The general conclusions reached by these observations were, that in the United States there is a class of physicians who, in ability, knowledge, and skill in the application of their art, are not excelled by any similar class in Europe, but that in this country this class is so diluted and obscured by the much larger class with superior pretensions and inferior knowledge and skill, who keep themselves so prominently before the public as to overshadow the better class and give a superficial appearance of inferiority to the profession as a whole.

By the uncontrolled multiplication of graduates of medicine here, the profession is overcrowded with indifferently educated men far beyond the demand or necessity for their services, and far beyond the proportionate number in any other nation. If this struggling surplusage and its influences be subtracted, the profession of medicine in this country is probably nowhere excelled.

The condition of pharmacy in the United States appears to be fairly parallel to that of medicine. In no country are there any better medical supplies than in this. Indeed, with respect to both quality and management, there is a strong probability that there is a superiority here. But, there is certainly no country more abundantly supplied with bad drugs, nor with the ability and skill to put them in the place of good ones. In most European countries pharmacy is so controlled that it is not very easy to get bad medical supplies, while in this country, with pharmacy almost uncontrolled, it seems not very easy to get good ones. With good and bad material in equal abundance, the pharmaceutical ability and skill which constitute good pharmacy in the one case make very bad pharmacy in the other, and against this last the European control measurably protects European physicians and their patients. Here there is probably better pharmacy and more of it than there; but here there is an enormous amount of bad pharmacy to contrast with a very little there.—*Squibb's Ephemeris.*

Foreign University Intelligence.—*Berlin.* Prof. Westphal has just celebrated the completion of his twenty-fifth year as teacher in the University. The total number of students, including all the faculties, is the highest on record, being 5357. Of these, 1297 are medical students.

Göttingen. The 150th anniversary of the founding of the University will be held next year.

Leipsig. Prof. Credé has intimated his desire to resign the charge of the Obstetric Institution, which he has held for thirty years.

St. Petersburg (Military Medical Academy). Privatdocent Dr. A. Beltsoff has been appointed by the Conference (Senate) to take temporary charge of the Surgical Clinic of the late Prof. Kolomnin. It is stated by the St. Petersburg correspondent of a Riga paper that Prof. v. Bergmann, of Berlin, has declined an invitation to the St. Petersburg Chair.

The Pasteur Institute.—The Paris Municipal Council have agreed to M. Pasteur's application for a 99 years' lease of 2500 metres of ground adjoining the site already granted for his Institute. The ground rent is fixed at four francs per metre.

Fund for the Maintenance of Guy's Hospital.—The meeting held at the Mansion House on December 21st to initiate the movement for obtaining the capital sum of £100,000 for the benefit of Guy's Hospital, was addressed by His Royal Highness the Duke of Cambridge, Cardinal Manning, Mr. Leopold Rothschild, and the Bishop of Rochester. It was stated that the annual revenue of the hospital had, owing to agricultural depression, declined from £41,000 to £26,600, and that it had been necessary to reduce the number of beds in use from 650 to 400. Cardinal Manning spoke strongly against the French system of government hospitals, on the ground that the department which had the management of the hospitals was always ruled by political influences; that the system checked the flow of charity; and that it substituted a mechanical method for "the dynamic power of charity that had governed and civilized the world." It was announced that the governors were willing to publish a full annual balance-sheet if they were entrusted with public money. The fund already amounts to over £17,000.

ORIGINAL LECTURES.

BLACK CATARACT.

A Clinical Lecture delivered before the School of Ophthalmology, at the Central Dispensary, Washington, D. C.

BY SWAN M. BURNETT, M.D.,

DIRECTOR OF THE OPHTHALMOLOGICAL AND OTOLOGICAL CLINIC

GENTLEMEN: While it is our main purpose in these clinical lectures to bring before you the commoner forms of eye-disease, such as you will be most likely to meet with in the ordinary routine of your practice, we shall not allow to pass by unnoticed some of the rarer forms of ophthalmic affections, particularly those in which the diagnosis presents points of difficulty. In ophthalmology, as in internal medicine and general surgery, correct diagnosis lies at the basis of successful therapeutics, and the close study of the differential diagnosis of the various affections of those parts of the organ of vision open to inspection by the naked eye, will be of much greater value to you in these preliminary studies than watching the most skilfully performed extraction of cataract.

But the diagnosis of cataract should be a matter of great interest to you, even though you may never make an attempt to operate for one. It is a common practice —and a very good one—for patients to apply to their family physician whenever they have any trouble with their eyes, in order that he may direct them where to go in case he does not consider himself competent to treat it. Should one of your patients so apply to you, it would be very humiliating, if you had diagnosticated a cataract, to have the ophthalmologist to whom you referred him find an atrophy of the optic nerve, or glaucoma. This a common experience at this clinic. Patients have been sent here by physicians, having made all their arrangements to remain for an operation, no doubt existing in the mind of either physician or patient that it was a case of cataract, and that at the end of two weeks the patient would return home restored to sight. It is not a pleasant thing to have to tell these poor people that their physician was mistaken—that their lenses are perfectly clear, and that an operation cannot bring their sight back to them.

And, generally, the existence of cataract is readily determined; so readily, in fact, that most intelligent laymen know, from the appearance of the pupil, when the lens is opaque. At a distance of many feet the white appearance of the ordinarily black pupil proclaims the presence of cataract. Not, however, that all white spots on the "black of the eye" are cataracts. Mistakes in this particular are, perhaps, more frequent than of the opposite kind. A great many people, and, I am sorry to say, some physicians, regard any white opacity on the anterior part of the eyeball as a cataract.

The diagnosis of cataract is, as already stated, under ordinary circumstances, a matter of no difficulty whatever. A simple inspection will show at once a whitish opaque substance occupying the pupillary space behind the iris. This is particularly the case in children and younger adults affected with cataract and with the traumatic form, where the opaque lens is almost white, reflecting as it does nearly all the light that falls upon it. The softer the lens substance—that is, the more water it contains—the more heterogeneous and less compact are its particles, and the more light it throws back, just as the fine crystals of snow held loosely together are whiter than the compact ice.

All cataracts, however, are not soft and white, and in proportion as they become denser they reflect less and less light and the whitish appearance is less and less marked. For the diagnosis of cataracts such as these, a simple inspection will not always suffice, but recourse must be had to an illumination of the pupil by the concentration on it by means of a convex lens of two or three inches focus, of the light of a flame placed to the side of the eye. This method is usually known as "oblique illumination" or "examination by the oblique light." Under the examination any irregularity in the density of the lens generally reveals itself very readily as whitish or grayish spots or lines on the black background. In making this examination, there is one error to be guarded against, into which the inexperienced is very likely to fall. In persons advanced in life the pupillary space under the oblique illumination is not black, but greenish-gray, quite a sea-green in some cases, resembling, I fancy, somewhat the appearances the older writers meant in their descriptions of "glaucoma." This change in the aspect of the pupil does not always, in fact, very seldom, mean any great loss of transparency, as an examination with the ophthalmoscopic mirror will show at a glance. It signifies a certain amount of condensation or sclerosis of the lens-fibres which may be considered as a kind of natural evolution on the part of the tissue in common with the changes in other parts of the body due to advancing age. Its peculiarity is that it is perfectly even, in contradistinction to the opacity of cataract proper, where the opacity is, in the incipient stage, irregular, and whitish with no tinge of green. To make, however, assurance doubly sure, the diagnosis should not be considered as absolutely final until the ophthalmoscope is used. If there are any opacities in the lens, these will show themselves as black spots or lines on a reddish ground, when the light is thrown into the pupil from the ophthalmoscopic mirror. If the pupillary space is evenly illuminated you may be sure there are no opacities in the media—certainly the anterior media—that are at all serious. By one of these three methods, therefore, simple inspection, oblique illumination, or the ophthalmoscopic mirror, any ordinary case of cataract can be diagnosticated readily and with ease.

But occasionally there arise cases where a differential diagnosis is a matter of no little difficulty. Quite a

number of the text-books written since the invention of the ophthalmoscope, will tell you that the existence of an opaque lens can be determined by means of this instrument, and the oblique illumination, with a certainty which admits of no exception. Happy would we be if that were so, and the purpose of this clinical lecture is to point out a class of cases in which this great instrument is not always sufficient in itself to establish a diagnosis.

For this purpose I will ask you to examine with me this woman, Mrs. X., who is thirty-eight years old. She came to the dispensary a week ago, being led by her daughter. In the right eye she had been blind for a number of years, but vision in the left had been sufficient to enable her to get about and perform her household duties until within the last three months. She is now blind in that. If you look at her pupils, you will see that they are black, with no appearance of gray, green, or white, whatever. You will observe this peculiarity about the eyes, however, that the iris in both oscillates or trembles when she moves the eyes. This is evidence of a lack of posterior support to the iris, and indicates a slight dislocation of the lens. Proceeding now to a further examination with the ophthalmoscope, we throw the light from the gas-flame, by means of the mirror, into the pupillary space. There is no reddish reflex—all is black. We are certain now that there is opacity somewhere in the refracting media, but its exact locality is not revealed to us by the mirror alone. It might be anywhere from the aqueous humor to the retina. We now concentrate the light on the anterior portion of the eye by means of a strong convex lens. The cornea is clear, and the aqueous humor unclouded, for the iris is seen clearly. The pupillary space is black, to the ordinary observer it would seem perfectly black, but an oculist of experience would find a very slight tinge of gray, such as is usually found in the pupils of persons advanced in life. The pupils have been dilated with atropine, and as far as can be seen toward the periphery there is no irregularity, no striation, but everywhere an even, smooth field of black. Such an appearance is so different from that of the ordinary cataract which you have seen here so often, that it would probably never have occurred to you to suspect that it was a cataract. But it is evident from the examination with the ophthalmoscopic mirror that there is an opacity somewhere posterior to the iris which obstructs the passage of light, and this obstruction must be either in the lens or vitreous humor.

How shall we determine in which of these two tissues the obstruction resides? The ophthalmoscope and oblique light, as we have seen, not giving us definite answers, we must resort to a test which was the first one used to determine, in a scientific manner, the presence of the lens in the eye as well as its transparency. It is called among the older writers—that is, those in the preophthalmoscopic era — the "Purkinje-Sanson," or simply the "Sanson" experiment (in honor of the man who first described it),[1] or the "catoptric test." The test is based upon the well-known laws of reflection from curved surfaces. The lens being a body with curved surfaces placed in a medium (the humors of the eye) of less density than itself, must furnish, in accordance with these laws, two images of an object held in front of it, just the same as an ordinary convex lens held in the air.

If we place a candle in front of a healthy eye, we see three images of the flame when it is held a little to one side of a line passing through the centre of the observed pupil and our own. The first of these, on the side next the candle, is a bright erect image of the candle-flame reflected from the convex surface of the cornea; the second is the blurred outline of the erect image reflected from the anterior convex surface of the lens; the other very small—so small indeed that it can be very readily overlooked and can be seen distinctly only by means of a magnifying glass,—and inverted, comes from the concavity in the vitreous in which the posterior wall of the lens rests. If the candle is moved up and down, the images also move; the two erect ones from cornea and anterior surface of the lens in the same direction as the candle, the small inverted one in the opposite direction, as do all images formed by concave surfaces.

It is perfectly evident that in order for the small inverted image to be formed, and consequently seen, light will have to pass through the lens. Its absence, therefore, is conclusive evidence of an obstruction to the passage of light—lenticular opacity, in other words.

We will now apply this test to the eyes of Mrs. X. Holding a candle about eighteen inches a little to the left of a line passing through the centre of a pupil, we see the bright erect image of the flame from the cornea, and the blurred quite indistinct image from the anterior surface of the lens, but nowhere the small bright inverted image from the anterior concave wall of the vitreous, such as we saw in the eyes of the gentleman with a transparent lens, on whom we just now applied the test. The diagnosis is, therefore, established beyond peradventure—the patient has cataract.

This, gentlemen, is not the first time that we have been compelled, in this clinic, to resort to this old method of diagnosticating cataract. A case of even greater difficulty than this one presented itself, in accordance with that law which seems to govern the occurrence of rare cases of disease, only two weeks ago. Some of you, who were present at the time, will doubtless remember her. It was in a colored woman of sixty-eight years, whose left eye was fairly good, but whose right had been blind for some time—but how long we could not find out since an intelligent account of it was not to be had. Both pupils were of the same degree of blackness, and were quite as black as those of her daughter of twenty-eight years, who accompanied her. The ophthalmoscope showed, not a perfectly black pupillary reflex, but a faint shimmer of red or brown, though perfectly uniform and even. The pupil was dilated with atropine, and a careful examination made by the oblique light; and though the whole of the pupillary space was carefully and repeatedly examined, even with a magnifier, not a trace of striation or irregularity of any kind whatever could be found, except at the lower inner corner, where there was a single white projection into the pupil of about one millimetre, evidently in the capsule, as it was immediately under the iris.

It curiously happened that the same day another patient presented herself with an eye having exactly

[1] Purkinje: Beobacht. u. Versuche z. Phys. d. Sinne. Berlin, 1825.

the same appearances under the ophthalmoscope and oblique light, barring the opacity in the capsule. The vision in the affected eyes of these two patients was about the same—that is, there was a good perception of light and normal projection, but no power to distinguish even large objects, though held close to the eye. I do not hesitate to say that without the aid of the "catoptric test" it would have been impossible for even an expert to have made a differential diagnosis in these two cases. We applied, in the presence of some of you, this test, and demonstrated to the satisfaction of all that the small inverted image was present in the one case and absent in the other, and so absolutely did we trust the finding of this examination that we at once sent the one case to the Garfield Hospital for operation, while the other was put under treatment for a choroiditis with serous effusion into the vitreous. The case of the colored woman sent to the hospital, confirmed, under the operation, our diagnosis in a most satisfactory manner. It was my desire to extract the cataract in the capsule if possible, for I wanted to subject the lens to some examinations for determining its exact character and constituents. In the accomplishment of this I was most fortunate. Latterly I have been making all extractions without an iridectomy whenever I deemed it safe, but to extract in the capsule is much easier and less dangerous with an iridectomy, and in the present instance, after making a large incision after the manner of de Wecker, I excised a rather large piece of the iris and succeeded, by manipulation, in delivering the lens in the capsule without the loss of a single drop of vitreous. The lens was at once measured and found to be 8.5 millimetres in its equatorial diameter and 2.7 millimetres in its antero-posterior diameter. Those measurements included the capsule, and fall only a little below the measurements of a normal adult lens. When held against a black background it appeared perfectly black, but when viewed by transmitted light it gave a rose-amber color at the periphery which gradually and evenly deepened into a dark reddish-brown at the centre. It was placed in a neutral fluid and taken at once to the Army Medical Museum, where Dr. Gray was kind enough to examine it under the microscope. He found some folding of the capsule, but the lens structure itself was perfectly uniform; neither by transmitted nor reflected light could any irregularity in density be made out under the highest powers that could be applied. There were no pigment granules anywhere. I then took it to the chemical laboratory at the National Museum and Prof. F. W. Clark was good enough to examine it spectroscopically. The examination was made with a Hoffmann's hand spectroscope, and Prof. Clark assured me that any hematine could be excluded, for there was an entire absence of the blood absorption bands. There was, however, a cutting off of the whole of the blue end of the spectrum.

This last is exceedingly interesting, taken in connection with a clinical phenomenon which is quite frequently observed in persons operated on for cataract. Only a few weeks ago I operated on a woman for cataract having a hard nucleus. As soon as the eye was opened, after I had cleared the pupil of some remaining corticalis, she exclaimed: "Oh! how blue every thing looks." Such an experience is very common with intelligent patients who are accustomed to observe their sensations closely. What is the cause of it? A spectroscopic examination of the nucleus removed from her eye, I think, readily explains it. It was exactly the same as in our specimen of "black cataract." All the blue rays of light are absorbed by the lens, and only the rays belonging to the red and yellow end of the spectrum struggle through and reach the retina. This has continued for years, and the parts of the retina or brain which take part in the perception of blue have remained dormant and resting, while the stimulation of the yellow and red rays has continued all the while. Now, when the lens is removed and a flood of white light containing all the colored rays in due proportion, is admitted into the eye, the blue rays are perceived so strongly as to overpower the others, and give a predominating color to all objects. It is analogous, or identical, with the phenomenon observed when you look fixedly at a cross or other object of a red color for a few seconds and then direct your gaze to a white wall, or sheet of paper. The cross is seen for a short time on the white surface as green or bluish-green, according as the original color was red or yellowish-red.

After the occurrence of the first of these cases, and being by it made aware of the great difficulty that would be experienced by a young practitioner in determining the seat of the opacity, I examined all the text-books to which he would be likely to look for information, to find how far they would give him assistance in his time of need.

There is almost a unanimity of silence as to the catoptric test, in all the text-books published since 1851, the date of the invention of the ophthalmoscope. Of our American text-books, Alt, Schell, and Noyes do not mention it at all in connection with cataract. Williams mentions it, but disparagingly—"It is not very easy or certain of application," he says; and Mittendorf mentions it only incidentally. Of the English works, no notice of it is found in Nettleship, Swanzy, Wolf, or Macnamara. Wells mentions it, but says it is not used now; and Haynes Walton, in the edition of his work published in 1861, dismisses the subject with the following sentence, "Purkinje's candle or the catoptric test, so much vaunted as a means of distinguishing incipient cataract, is really valueless, but as it enables us to pronounce with certainty whether the lens is absent or not I introduce it here."

Of the foreign text-books that I consulted, Schweigger, Massillon, and de Wecker pass it over in silence, while Meyer says that "the formerly much used catoptric test of Purkinje-Sanson is *ausser Gebrauch gekommen*." On the contrary, nearly all the works published prior to the invention of the ophthalmoscope give it great prominence as a method of diagnosis.

While thus valuing to the fullest extent the brilliant discoveries in diagnostic methods in more recent times, let us not undervalue or neglect those other means on which our fathers in ophthalmology wholly relied. We cannot have at our command too many methods of differentiating one form of disease from another.

Concerning the essential character of black cataract, its etiology and frequency, there seems to be much difference of opinion. Some modern writers do not mention it at all. You will not find it alluded to in the text-books of Alt, Nettleship, Williams, Noyes, Swanzy, or Wolf, and those that do so, for the most part, give it but

a passing notice. Mooren, in his tabulation of 108,000 eye cases,[1] gives 6536 different affections of the lens which had come under his observation, but among them not a single case of *cataracta nigra* is recorded. On the contrary, Dr. Knapp, of New York, writes me that he has seen "dozens of cases of *cataracta nigra*," one of which he had just extracted at the time he wrote. Dr. Chisolm, of Baltimore, whose experience in cataracts is probably as large as any one in this country, says that in 477 cases of cataract he saw in the last twelve months, there was one case of typical black cataract, but even in this there was some striation visible by means of the oblique illumination. Dr. Ayers, of Cincinnati,[2] in his paper on the subject, says that Dr. E. Williams in his vast experience has seen but two cases. Armaignac[3] is of the opinion that it occurs once in about 500 cases of lens trouble. Mackenzie[4] says, "I have seen a few cases of lenticular cataract in which the opacity was so very dark that without close examination the disease might have passed without detection; on concentrating the light on the pupil the lens appeared striated. Such cases have been called *black cataracts*." Desmarres[5] gives an account of a single case he saw in his practice. Dupuytren and Delpech never encountered a case in their immense practice, and others of equal prominence have denied its existence.

Even as late as 1853, the *Dublin Medical Press*, in commenting upon Alessi's case of black cataract, reported in the *Bulletino delle Science Medicale*, says: "The ghost of a black cataract has been haunting the study of the ophthalmologist time out of mind, never to be caught, and seldom to be perfectly seen. Here it is again, 'the field of the pupil quite dark,' 'the appearance was of a dull, dusky color,' 'a black tint,' 'a reddish-black,' 'a dark color,' which is lost by maceration in alcohol,' and as like a 'flattened bog-berry' as a sea-serpent is like a whale."

My own opinion, gathered from reading considerable literature on the subject, is that brown, partially black, cataracts are rather common, but that pure black cataracts, particularly those of the character of our first case, which show absolutely no striation by oblique light, are extremely rare.

There is as little uniformity in opinions regarding the cause of the blackness of these cataracts as in respect to their frequency.

Desmarres's case (l. c.) was examined by MM. Gros and Lebert. The former found pigmentary granules and grains of colored matter in the cortex; while the same lens examined by the latter was found to have no grains of pigment, but a homogeneous browning of the lens fibres.

It is not at all improbable that the pigment and brownish granules seen by Gros, and also by others who have reported similar conditions, are due to the presence of the pigment of the iris and blood-globules which have adhered to the lens in passing through the pupil or coloboma of the iris.

The case reported by von Gräfe,[6] however, seems to have been somewhat different. It was in a man twenty years of age, who had had a blow on the eye. The nucleus was dark, almost black, with a spot of blackness on the corticalis, the greater part of the corticalis, however, being white. The lens showed, on examination after extraction, a quantity of pigment diffused and in spots among the lens fibres, all of which gave the chemical reaction of blood. He considers this case, and one other case of a similar kind which he relates, to be due to the imbibition of blood by the lens, following hemorrhage in its vicinity.

He relates, however, a second case, which seems to be identical with our first. It was in the pre-ophthalmoscopic days, and the pupil appeared steel gray, and the small inverted image in the Purkinje-Sanson experiment was lacking. The lens, on extraction, was of a dark amber color.

Müller's case[1] was very much like ours, except that there was a posterior synechia. A microscopic examination did not show any granules or pigment.

In the *Index Catalogue of the Library of the Surgeon-General's Office* there are fifty-one titles under "black cataract," not including text-books, and from a consultation of a majority of these articles, and of the most prominent treatises on the eye, I am satisfied that two very distinct forms of lens affection have been described under the term *cataracta nigra*. In one there is undoubted infiltration of pigment into the lens-substance, probably originating from a hemorrhage in the vicinity of the lens, which should be called *cataracta pigmentosa*. In the other, the true *cataracta nigra*, there is no infiltration of pigment, but simply a sclerosing or hardening of the whole of the lens, of the same character as in the nucleus of the ordinary "hard cataract." In other words, the lens becomes all hardened nucleus. In proportion as this sclerosing process is even and smooth, leaving the lens fibres of the same density throughout, in that proportion will the lens reflect less and less light, and the pupil offer less and less the usual white appearance characteristic of the common form of the disease, and show fewer striæ and irregularities under oblique illumination. I think there can be no doubt that such black cataracts are longer in forming than the others, and consequently we should expect to find them more frequently in persons well advanced in life.

The prognosis for operation in such cases does not seem to be worse than in the other forms. In our own case the patient made a faultless recovery, and has excellent vision. In operating, however, the fact must be borne in mind that the lens is large, and the corneal [illegible] should be correspondingly ample.

NEPHRORRHAPHY AND NEPHRECTOMY.

[illegible] M.D.,

[illegible] PENNSYLVANIA

CASE I. *Nephrorrhaphy.*—I. B., aged thirty-two years, married, a native of Pennsylvania, was admitted to the medical ward of the University Hospital, October 13, 1883, with the following history:

[illegible] Opl. [illegible]

His occupation was that of a salesman. For some time he had been employed in a furniture store and enjoying perfect health. In the fall of 1878, while lifting a heavy piece of furniture, he felt something give way in his back, followed by a sharp sickening pain in the same region. His suffering was so great that he was unable to continue his work.

When admitted to the hospital he complained of a severe dragging pain in the lumbar region which extended downward to the caput coli, was paroxysmal, and always aggravated by any unusual effort. Dimness of vision was also present, though a careful examination of the eyes failed to disclose any abnormality whatever. In the left lumbar region and extending forward to the umbilical there was a tumor having the general conformation of the kidney. This could be readily felt through the abdominal parietes, though occasionally it would disappear beneath the ribs, and could only be made tangible by the manipulations of the patient.

At the time of his admission albumen in small quantities was detected in the urine, but no casts. The former disappeared very soon or after a few days of quiet in the hospital ward. The diagnosis made by Prof. Pepper, under whose care the patient was placed, was floating kidney. Various measures were adopted to fix the organ but without avail, and at the end of some months he left the institution without realizing any material benefit. The following October, finding himself growing worse, he returned to the hospital and came under my care. Several examinations of the urine were made, none of which gave any evidence of structural change in the kidney. Nephrorrhaphy was proposed as the only procedure promising relief. The proposition was accepted, and on the 10th of October the patient was placed on the table; the kidney exposed through the loin and the organ stitched in the wound by means of animal threads passed through its capsule. A drainage tube was introduced and the incision closed by sutures. The operation was made under strict antiseptic precautions and resulted in prompt union. After the first twenty-four hours the temperature remained normal, and on November 5, 1884, the patient was discharged.

CASE II. *Nephrectomy.*—On April 21, 1885, he again returned to the hospital with a renewal of all his old symptoms in so aggravated a degree as not only to incapacitate him for his occupation, but requiring the use of morphia to obtain a reasonable amount of comfort. He stated that while engaged at some work he was seized with lumbar pain and felt that the kidney had left its moorings. An examination verified his fears, as the organ could be distinctly recognized in front, through the abdominal parietes.

Nephrectomy was now proposed, and to this the man readily acceded, and on the 23d of April the operation was done by the lumbar incision, the wound closed by sutures, and a drainage tube brought out at the lower angle, the whole procedure being executed under strict antisepsis. The temperature at no time rose above 100°, and the urine varied in quantity from twenty five to forty-five ounces daily. At the end of fourteen days the drainage tube was removed, and on May 21, two days less than four weeks, the patient returned to his home. For some time a small sinus remained, which ultimately closed after the discharge of a loop of thread which, I believe, was the ligature that had been used to secure the renal vessels. The patient continues well up to the present time.

The operation of nephrorrhaphy has not been attended with the success which at one time was anticipated, the organ in most cases breaking away and wandering into its former abnormal position. Still I do not think this mode of treatment should be too hastily abandoned. I believe that with some modification of procedure better results will be obtained. That which I would suggest would be, instead of tearing away too freely the fat which surrounds the organ, simply to open a crevasse sufficiently large to admit of the kidney being slipped through, and then with the mass of adipose tissue in front, let the latter, instead of the kidney, be stitched to the edges of the wound.

CASE III. *Nephrectomy.*—Mrs. H., aged sixty years, white, married, was admitted to the private department of the University Hospital, Nov. 19, 1886. Nine months previous to admission she had experienced pain in the left iliac region accompanied by dragging sensations in the corresponding loin. These symptoms increased in severity; she began to lose flesh and strength and had become exceedingly nervous. On examination an irregular swelling was readily discovered in the left lumboiliac region, movable, sensitive to handling, and apparently about twice the size of a healthy kidney. The urine contained neither renal elements nor albumen. The absence of renal epithelium and of blood in the urine, the progressive loss of flesh, and a suspicious color, left me somewhat undecided both as to the organ involved (kidney or ovary) and the benignity of the tumor. Still I inclined to the opinion that the growth was an enlarged kidney. As the woman's health was failing rapidly, laparotomy was proposed and accepted. Assuming that possibly the disease might prove to be ovarian, this operation was, under the circumstances, deemed best. On November 20 the patient was placed on the operating table, and the abdomen opened by a median incision three inches in length, bringing at once into view a large irregular-shaped mass which, on a closer examination, proved to be the kidney. Its peritoneal investment was carefully stripped off, the ureter and vessels after being securely ligated were divided and the organ removed. After applying the animal thread to two or three small bleeding vessels, the cavity of the belly was washed out by warm water, previously well boiled, the wound closed by interrupted sutures, covered with a compress of carbolated gauze and a pad of salicylized cotton, and the whole secured in place by a broad flannel binder. During the operation the spray was allowed to play over the abdomen and a solution of the bichloride (one to five thousand) was used for the sponges. The amount of daily urine could not be accurately ascertained as a certain quantity escaped in the bed before the urinal could be adjusted, but that which was passed voluntarily and collected varied

from ʒix to ʒxxij and on one occasion rose to ʒxxx. The temperature oscillated between 98° and 99⅕°, and on only two occasions did it rise to 100⅖°, subsiding at once to 99⅖° after the bowels had been relieved by an enema. On the 28th the stitches were removed, the wound having healed in its entire length. After the 30th the patient sat up daily; indeed, from the time of the operation there were present no unfavorable symptoms whatever. On the 7th of December while sitting up she was suddenly seized with severe abdominal pain, which was attributed to a cold taken in changing her room. This increased in severity, though unattended by any abdominal distention. The urine had rapidly fallen off in quantity, soon followed by suppression. A hypodermatic of morphia one-quarter grain, atropia one-hundredth grain relieved her suffering, but she soon sunk into a profound stupor and died.

As an autopsy was not allowed, the cause of death in this case remains somewhat obscure. It is difficult to conceive of peritonitis setting in at so late a date from ordinary causes, as the patient was then in her third week, and there had been no error of diet or other indication to account for such an attack, unless the cold, which necessitated a change of rooms, may have done so. The more reasonable explanation for the unexpected termination of the case, I think, may be referred to the remaining kidney. The organ removed contained a number of cysts, some of them very beautiful illustrations of pearl cysts. These cysts did not appear to communicate with the pelvis, and hence the absence of renal elements in the urine. It is, therefore, more than probable that the other kidney was undergoing a similar degeneration—as bilateral cystic disease of these organs is quite common—and that it was unequal to the work of supplementing the functions of its fellow, in consequence of which uræmic poisoning followed, and this may have developed the peritonitis if such a condition was present.

SOME FACTS RELATING TO THE EFFECTS ON MAN OF FUEL- OR WATER-GAS, AS OBSERVED IN THE RECENT CASES OF POISONING AT TROY, N. Y.

By R. B. BONTECOU, M.D.,

The introduction into cities of fuel- or water-gas for domestic and manufacturing purposes is becoming a subject of interest, not only on account of its cheapness and cleanliness, but more especially on account of its poisonous nature, and from the fact that it is quite odorless, and produces its deleterious effects before there is any suspicion of its presence.

A number of accidents have occurred since its introduction here, and very recently three fatal cases in one house. No serious cases of poisoning have, to my knowledge, occurred to those who used the gas for domestic or manufacturing purposes, but all the cases of sickness and death attributed to it here have occurred in houses on the street on which the mains are laid, and where, from presumed leakage, the gas has permeated the soil beneath the frozen earth into the cellars, and thence up into the buildings. In five stores located near one of the mains, the clerks and porters, about fifteen persons in all, were so seriously affected on one day as to be obliged to have medical aid, two or three losing consciousness for a short time.

On the evening of January 16th the inhabitants of a row of three-story brick buildings were almost all seriously overcome by the gas. When the cause was discovered the people of the vicinity were aroused by the police, who found many sick, and on one flat all the occupants dead. The opening of windows and doors for the remainder of the night saved many lives. The persons who were found dead had probably been so for some hours, as "rigor mortis" was present in all. Their fires were burning in the stoves and their lamps still lighted on the tables. One of these cases was an old woman, who was found sitting in a chair by the stove, with her head thrown back and in her hand her artificial teeth, as if she had been vomiting. Her daughter, a person about forty-five years old, lay dead on the floor near by, with a slop bucket at her side, as if she had also been vomiting. The third, a man about forty years old, sat upright on a lounge with his head reclining on his shoulder as if death had been sudden and painless. The expressions of the deceased were placid.

I was present and assisted at the autopsies of these people made by Dr. John W. Morris, about eighteen hours after death. Their bodies appeared to have been in good health and well nourished, and there were no external marks of violence nor any evidence of commencing decomposition. The faces of the two found sitting were pale and exhibited a placid expression, eyes closed, pupils natural, neither contracted nor dilated, conjunctivæ clear.

The woman found on the floor in dorsal recumbency also had a peaceful expression of the face; her tongue was slightly protruded between her teeth, and the neck and one side of the face were discolored by florid hypostatic congestion. Her pupils were natural and conjunctivæ clear. On section the muscles were noticed to be unusually red—a bright cherry-red. The lungs were free from adhesions, and filled their cavities completely, were crepitant throughout, and of a cherry-red color. On section serum flowed freely, but there was no œdema. There was no unnatural amount of fluid in the pleuræ or in the pericardium. The heart was empty and on section fluid blood escaped from the vessels. The left ventricle was contracted and firm. The right not contracted and, together with the auricles, rather flabby. Valves were all normal.

The abdominal viscera were all in a normal condition. The stomach contained a moderate amount of well-masticated food without any unnatural odor, and there was no odor of alcohol or beer. The intestines were natural as to distention and contents, but were of an unnaturally pink color throughout. The kidneys, spleen, and liver were all normal. The gall-bladder contained five calculi. The blood everywhere was fluid and no coagulum was seen.

The body of the old woman presented the same unnatural vivid redness of all the solid portions except the adipose tissue. The lungs filled their cavities completely, and were crepitant throughout. Heart

was empty, valves normal, and blood everywhere fluid. Abdominal viscera were all normal; stomach contained a small amount of liquid food, and no odor of liquor, or of anything unusual. Intestines were of a decided pink color. Kidneys, spleen, and liver normal, except that they were too vividly red in color.

Autopsy on the man presented the same unnatural vivid redness of the textures, except the adipose. His lungs filled their cavities, and crepitated throughout. Heart empty, valves normal, blood everywhere fluid, and no coagulum. Stomach contained a small amount of well-masticated food, without odor of liquor; intestines of a pink color. Kidneys, spleen, and liver normal. Brain membranes were vividly red all over, and an unusual amount of serum escaped when they were opened; the white portion of the brain was studded with an unusual number of red points on section; there was no coagulum in any part of the brain, and both in the sinuses and elsewhere the blood was fluid.

On opening the cavities of the first woman I put my face close to the parts, to obtain a peculiar faintly alliaceous odor which I had perceived and which I had never before recognized. This presently gave rise to a sense of faintness and severe epigastric pain, so much so that I was for half an hour obliged to stop work, and the resulting headache and feeling of indisposition lasted all day and evening. I have made and been present at several thousand autopsies, and was never before affected unpleasantly, and, as I was in good health at the time, ascribe it to inhaling the poisonous gas respired by the woman and exhaled at the autopsy from her tissues.

I have made inquiries of several of the persons who resided in the buildings and who were affected by the gas, as to their symptoms, and all stated that they felt either pain in the head, or a sense of tightness like a band around it, and also faintness and giddiness until they became unconscious. A few had epigastric pains and vomiting, and quite a number whom I did not personally see are reported to have suffered from the same symptoms.

Fuel-gas is not used for illuminating purposes; it burns with a pale bluish flame of great heating power, and it is produced by decomposing the vapor of water in the presence of burning coke or coal. Its constituents are reported to be hydrogen 56, carbonic oxide 44 parts, in 100.

P. S.—Since writing the above I learn that a gentleman who was exposed to the gas, in his store, about January 7th, was confined to his house in consequence for a week.

On the occasion of the fatal accident, a gentleman living in the third story of a house in the same block was awakened, about eleven o'clock, by the strange conduct of his dog. The animal made unusual noises like the act of vomiting, and whined and barked in a peculiar way, which awakened the man and his wife, who then discovered that they were sick, and that other occupants of the building, also, were sick. Probably if the dog had not aroused them, the inhabitants of this whole block of buildings would have perished.

A YEAR'S WORK IN OVARIOTOMY.[1]

BY WILLIAM GOODELL, M.D.,
PROFESSOR OF CLINICAL GYNECOLOGY IN THE UNIVERSITY OF PENNSYLVANIA

IT was my intention at first to embody in one article all my year's work in laparotomy. But, since the number of cases amounts to fifty-nine, the consideration of which would make too bulky a paper, I have decided to limit myself to my cases of ovariotomy, which numbered twenty-nine, with three deaths. These cases I now present in a tabulated form, and let me here premise that they were not selected, but were taken just as they came to me. The only case on which I refused to operate, was one which had, besides an ovarian cyst, a cancer of the cervix uteri. Let me also add, that in every case save one—No. 189—the operation was completed, no matter what difficulties were encountered, so that I have no exploratory incisions to report on the score of ovarian cysts.

Of these twenty-nine cases, twenty-three were operated on at my private hospital, four at the homes of the patients, and two at the Hospital of the University of Pennsylvania. Not one of these three deaths was due to septicæmia, but to the grave complications in each one, and a few words of explanation are needed. Before the death of Case No. 178 I had had in succession twenty-two successful cases, and afterward a series of eight cases before the next death took place.

No. 178 was a dreadful case of intra-ligamentous cyst. The lady, aged forty-three, first discovered the tumor in October, 1885, and since then it had grown rapidly. She suffered much pain from it, had greatly emaciated, and had finally become bedridden. She had consulted a number of experts, who had all pronounced the growth to be a fibro-cyst of the womb. I found a very large and immovable tumor, completely filling up the abdominal cavity, and bulging so low down in Douglas's pouch as to present at the vulva. Fluctuation was obscure, and adhesions were apparently universal. A prominence on the left side of the abdomen, and nearly on a level with the umbilicus, proved to be the fundus of the womb. The os uteri was drawn high up behind the symphysis pubis, as is often the case in uterine growths, and very rarely indeed in ovarian tumors. The sound went in five inches, and its tip in the prominence could readily be felt through the abdominal wall. The womb was immovable, and the tumor seemed to spring directly from it. My diagnosis was either a fibro-cyst of the womb, or a colloid ovarian cyst with close uterine connections, and with pelvic and general adhesions. In view of the very weak condition of my patient, the obscurity in the diagnosis, and the presence of formidable adhesions, I looked upon the case as a forlorn one, and I must confess to having felt a great reluctance to undertake the operation. She noticed this, and taxed me with it, saying, "You are afraid of your statistics." I replied that I had never refused to operate, no matter how ill the patient was, but that

[1] Read before the Obstetrical Society of Philadelphia, January 4, 1887.

I was afraid that she would die on the table. This, however, did not deter her, for she was a brave woman, and knowing that an operation was her only chance, she was determined to risk it.

On June 22d I operated on her, being aided by Drs. Jacob Roberts and W. Constantine Goodell. There were present also Drs. A. E. Malloch and John A. Mullin, of Hamilton, Ontario, and Dr. John W. Pickup, of Brockville, Ontario. The tumor turned out to be an intra-ligamentous and colloid ovarian cyst. It was attached to the whole of the ascending, transverse, and descending colon, to the small intestine, to the pelvis, to the bladder, and to the whole surface of the womb, measuring five inches. Over twelve inches of the right ureter had to be carefully dissected off from it. The lower portion of the cyst was included between the folds of the broad ligament, and it had to be carefully enucleated from it. When all the adhesions were severed the tumor came away without a pedicle. As the other ovary was merged in the large one, I could not tell which ovary was the diseased one; but, I think, from the implication of the right ureter, that it was the ovary of the right side. Very little blood was lost, for many pressure forceps and ligatures had been applied, and the peritoneal cavity was easily cleaned out. I put in a drainage tube, and was tying the last few stitches, when my patient's pulse suddenly flagged and she died in less than a minute. The operation had lasted two hours, and my great regret is that I did not let her partially come out of the ether several times during the operation; but her pulse and respiration had kept good.

Intra-ligamentous cysts, or those which grow between two layers of the broad ligament and carry them up as the cysts grow, present grievous complications, which tax the pluck and skill of the operator to the utmost. I had three of them during the past year, two besides the foregoing one. They were Cases 179 and 182. Each case required careful and patient enucleation, and the application of many ligatures. In the latter one, the cyst was also shelled out without a pedicle. They both got well without any drawbacks. It is in this kind of cyst that the operator is liable to tear the bladder, to wound the womb, or to rupture the ureter. In such cases one has to have all one's wits on the alert.

Case 187 was one of a uterine fibroid as large as the adult head, and a cyst of the left ovary weighing sixteen pounds. The right ovary, although sound, was removed on account of the presence of the fibroid. She did well for two days; then symptoms of obstruction set in, which could not be overcome, and she died on the sixth day, without any rise in the temperature. I cannot but think that pressure from the fibroid tumor was the main cause of the difficulty. Obstruction of the bowels after ovariotomy is the dread of all operators. It is due sometimes to the adhesion of a knuckle of intestine to the stump of the pedicle, to the abdominal incision, or to large denuded surfaces, and sometimes to an adventitious band from inflammatory exudation. Paralysis of the intestines from peritonitis will also cause it. I have had my share of such cases, of desperate ones too, and my rule is to get the bowels open as soon as symptoms of obstruction set in. Calomel and belladonna by the mouth, and turpentine by the bowels, are the remedies on which I rely, and they have never failed me, if my memory serves me no trick.

My last fatal case, No. 189, was an incomplete operation, and by many ovariotomists would not, on that account, have been included in the number of ovariotomies; but I think it fairer to do so. The lady was thirty-six years of age, married for nine years and sterile. The tumor was first noticed in June and had quickly developed. She had emaciated rapidly and suffered more or less abdominal pain. On November 19th, Dr. R. N. Downs, of Germantown, whom she had then consulted for the first time, called me in to see her. The womb measured four and a half inches, and was immovably fixed by a bilobed and dense tumor which seemed to spring from it. This tumor bulged low down into Douglas's pouch, and was knobby to the touch. There was evidently ascitic fluid present, but fluctuation could not be elicited from any portion of the tumor. The diagnosis was obscure, it lay between a soft myo fibroma or a sarcoma of the womb. From my standpoint, I was averse to an operation and advised delay. But two weeks later she suffered such agonizing pains, and such oppression from pressure, that I was forced to interfere, much against my will, especially so because a second examination had strengthened me in the idea that the growth was malignant. This pain was so great that the largest doses of morphia combined with chloral did not even allay it, and for the week preceding the operation she did not get any sleep.

On December 18th I operated, being aided by Dr. Jacob Roberts and by my son. There were also present Dr. R. N. Downs, Dr. W. Ulrich, of Chester, Dr. W. L. Taylor, of Philadelphia, and C. Laughlin, of Paris, Ill. A large amount of ascitic fluid escaped, and to my surprise an ovarian cyst, weighing about fifteen pounds, came into view. It was thick-walled, and did not collapse when its compartments were, one after the other, emptied, and I had to prolong the incision through and above the umbilicus. The omentum was adherent; it was of a purple color and its enlarged vessels looked like a bunch of earthworms. I now discovered that the cyst had not a pedicle, but that it ended in a short, hard, and brittle cancerous mass about the size of my fist. I should like then and there to have abandoned the operation, left the cyst *in situ*, and closed up the wound. But I had gone too far to recede. The cyst had been badly torn, for my hand had been inside of it to break up its septa, and it was bleeding profusely. To reach the cancerous mass forming the pedicle, I had to cut away the uncollapsed cyst, and, as I dared not use pressure-forceps for fear of crushing it up, I grasped it with my hand as best I could. But a good deal of blood spurted out, and the outlook was so ghastly that two of the gentlemen present became faint, and one had to leave the room. At last the bleeding mass was transfixed, and I tied it as well as I could, not daring to draw on the ligature too tightly, for fear of cutting through the friable nodules. Some bleeding vessels were also tied separately. A cyst of the left ovary, weighing about

ten pounds, now appeared. It collapsed upon the withdrawal of its contents, but it was so fastened to the womb, broad ligament, and Douglas's pouch by a mass of cancerous excrescences that I did not dare to disturb them. So I tied it as low down as possible, and cut off the free portion. If I am not in error, this is the first time that I have ever left behind a portion of the cyst. A drainage tube was put in, and the patient removed in a collapsed condition to her bed. She rallied sufficiently on the next day to converse with her family, but much bloody fluid escaped from the drainage tube, and she died in twenty-six hours after the operation.

In the foregoing case, had I known the complications, I would not have operated. But I unhesitatingly assert that, when possible, malignant tumors of the ovaries should be removed. For the improvement which follows is usually something remarkable, and years may elapse before the disease returns. In one of my cases four years of excellent health elapsed before the cancer came back. In such cases both ovaries should always be removed. Two cases in point are Nos. 165 and 180. In each a malignant colloid cyst had burst and had infected every abdominal viscus. In the latter case, indeed, the colloid poison had penetrated even into the abdominal wall through the opening made fruitlessly with a large trocar by her physician. Both patients were in a deplorable condition, with swollen feet, great emaciation, and general cachexia, yet the operation was followed by a marked amelioration of symptoms, and the women are still living and doing well, wonderfully well when one considers the amount of abdominal disease. A. Martin, of Berlin, mentions a case in which there was no return of the disease for seven years after the operation. Ten years after her first operation Schröder removed the second ovary. She lived one year and a half after this.[1]

But there is another class of cases in which malignancy lurks unsuspected in the most benign-looking cyst. Every year I meet with such cases. For instance, Case 149 was operated on, both ovaries being removed on June 13, 1885. She was greatly improved for two months, when cancer attacked the pelvic organs, and she died November 5th of the same year. Case 158 was operated on November 22, 1885, and she died from malignant disease of the pelvis in August, 1886. Case 150 promptly recovered from a double ovariotomy, to die a year later from metastatic cancer of the liver.

Out of my twenty-nine cases of ovariotomy, twenty one had adhesions, three had universal adhesions, and eleven very formidable adhesions. This is an unusually large proportion, and I attribute it to the fact that women in this country put off the operation as long as possible. For instance, Case 162 had the tumor for seven years, and at the time of the operation the cyst weighed fifty-eight pounds and was universally attached. Most of my patients come to me only when they are forced to do so by their sufferings or by their discomfort.

Out of my twenty-nine cases there were twenty of double ovariotomy. This is a large number, but I make it a rule to remove the second ovary in all malignant or suspicious cases, in all cases in which, from age, it can be of no use, in all cases in which incipient disease is manifest, and always when I am asked to do so by my patient. I willingly yield to their request, because I have seen several cases of heartrending disappointment, and even death from cystic degeneration of the remaining ovary.

The drainage tube is not a favorite of mine, and I try to dispense with it whenever I can. It is only in cases in which oozing goes on and the peritoneal cavity cannot be kept clean that I resort to drainage. The two cases in which it was used were of that character, and both ended fatally from the severity of the operation. I still adhere to strict Listerism, but while I use the spray, I now turn it away from the wound, and aim more to disinfect the room by it. It is an intolerable nuisance, and I intend soon to give it up in my private infirmary, reserving it for the impure air of a general hospital. The dressing for the wound, which I use, is gauze dipped in Keith's glycerole of carbolic acid, 1 : 8 parts. I have tried powdered iodoform, but it so adheres to the stitches as to make their removal difficult. I have, however, very recently obtained a 50 per cent. iodoform gauze which I shall soon use.

With regard to the question of performing ovariotomy during the catamenial flow, I have on several occasions been compelled to operate at that time, and have had no reason to regret such a course. Cases 176 and 182 were operated on during the monthly flow, and I have successfully performed oöphorectomy under analogous circumstances. Thomas Savage, a very successful ovariotomist, operates in any case whether the woman is menstruating or not, and finds no difference in the result.[1] The fact that a metrostaxis invariably takes place after a double ovariotomy would go to sustain the position which Mr. Savage takes.

Of the twenty-nine cases seven had been previously tapped, and all of them recovered. Yet I cannot too strongly condemn the too prevalent habit of indiscriminate tapping. Apart from the danger of exciting inflammation and septicæmia, and of producing adhesions, tapping may cause the whole abdominal cavity to become infected by the fluid of a papillary or of a colloid cyst. This I have seen several times, and Case 180 is one in point. The consultant in this case tried to evacuate the contents of a colloid cyst. Only a few ounces came away, the rest was too thick. But through the hole made by the trocar a large amount of the contained jelly oozed out into the abdominal cavity, hopelessly poisoning it. Even the abdominal wall immediately around the puncture was infiltrated with it.

SEA-BATHING A CAUSE OF EAR DISEASE.

By GORHAM BACON, M.D.,

[illegible]

It is a well-known fact that during the summer months, sea-bathing is a frequent cause of ear disease. Cold-water bathing, although of great benefit to many persons, frequently leads to chronic catar-

[illegible]

[1] British Medical Journal, April 14, 1883, p. 712.

rhal deafness, especially to those who have a predisposition to that disease.

The membrana tympani may be ruptured in diving or from the force of a wave striking against the side of the head and face; or, the cold water entering the auditory meatus, may not only set up an inflammation of the canal and drum-head, but may induce a tendency to chronic dermatitis and periostitis of the parts; the middle ear may also become secondarily involved, and occasionally the mastoid is affected from an extension of the inflammation. Still further, an inflammation of the tympanum may occur from water entering the middle ear through the Eustachian tube. I believe this latter frequently to be the explanation of an earache from sea bathing, as surf bathers are especially liable to have water enter the mouth and nasal passages. An acute catarrh of the middle ear is undoubtedly caused also in cold-water bathing from sudden chilling of the surface of the body when overheated, or from remaining in the water for a protracted period.

Children should be especially forbidden to "duck the head," as this frequently is the cause of catarrhal otitis media, and to prevent as much as possible a liability to ear disease while sea-bathing, the person should be careful to keep the head above water, and the auditory canals should be closed with non-absorbent cotton or wool.

Burnett, in his work on the ear, says: "It is noteworthy that no mammal but man goes voluntarily under water without being provided with a means of preventing the water from running into the ears. It is a fact well known to many, that hunting dogs taught to dive become deaf."

CASE I.—R., aged twenty-five, July 18th consulted me, and said that a week ago Sunday he went in bathing, and the following day the left ear began to pain him. Tuesday there was a slight discharge with some blood; he dropped some laudanum and sweet oil into the ear. The pain lasted till Wednesday morning; since then he has been annoyed by tinnitus, and the ear feels stuffed up. There is some autophony. He hears ordinary voice with the left ear.

Examination.—Left membrana tympani congested at the upper portion and slightly below; a small clot of blood on the drum-head, situated just below the umbo.

CASE II.—T. D., aged sixteen, June 26th. The patient said that three days ago he went in bathing, and directly afterward experienced pain in both ears, and since then the pain has been especially bad at night; he has also been suffering from headache.

Examination.—On removing some epithelium and cerumen from the right auditory canal, the membrana tympani is red and lustreless. Left membrana tympani also dull and congested.

CASE III.—Charles L., aged thirteen, July 3d. On Sunday, July 1st, he went in bathing; one hour afterward he had pain of a throbbing character in the left ear, which has continued ever since, with a sense as if something were stopping up the ear. There is no tinnitus or discharge.

Examination showed the left canal congested and tender; the upper portion of the membrana tympani (Shrapnell's membrane) red and swollen; no discharge or perforation.

CASE IV.—Joseph M., aged twenty-two, July 17th, bartender by occupation; he went in bathing July 13th, and the next day found that he had taken cold; he had pain of a pulsating character in the right ear, the pain being worse at night.

Examination.—The right canal contains some cerumen and epithelium; right membrana tympani red and denuded of epithelium.

CASE V.—Edward McC., aged ten, August 18th, says that six days ago he went in bathing, and on the following day began to complain of pain in the left ear, which has lately become very severe; two days ago he felt chilly sensations, and has been sick and feverish; there is no discharge.

Examination.—No pus in the left auditory canal; left membrana tympani red, lustreless, and tumid, especially around Shrapnell's membrane.

Aug. 21. The patient much worse; the pain very severe, especially at night, has not been relieved by the appearance of a purulent discharge, which commenced two days ago. There is marked mastoid pain, especially at night, the mastoid at apex being markedly tender to pressure. The patient looks very anæmic and weak, and before each onset of pain has chilly sensations, followed by fever; does not suffer, however, from headache or nausea. Temperature 101° F. at 5 P. M. Iodoform insufflated.

22d. The pain very much better, and apparently markedly relieved by leeching. He was also given tr. aconit. ♏j, and tr. ipecac. co. ♏ij, every two hours; also bowels were opened by a saline cathartic. The discharge is slight and the mastoid pain very much better. Very little discharge seen at bottom of the canal; membrana tympani is less congested; Politzer inflation gently applied, and iodoform insufflated.

25th. Very much better; no more mastoid pain; discharge very slight. He is quite deaf, and complains of a "stuffed up" feeling in the ear; his general appearance is much improved, and he is no longer pale. The discharge in the canal is very slight; congestion of the membrana tympani less marked; Eustachian tube pervious to Politzerization; inflation of the ear repeated and iodoform insufflated.

29th. No pain; he complains, however, of a slight buzzing tinnitus; discharge slight. Hearing distance, Watch $= \frac{0}{48}$. No discharge seen in the canal; the membrana tympani still red and covered with dry crusts. Politzer inflation repeated. Patient ordered the following tonic to be taken three times daily: ℞.—Potas. iodid. grs. v; syr. ferri iodid. ♏x; syr. hypophos. co. ad ʒij.

Sept. 4. Tinnitus less and very slight now. Hearing distance remains about the same. No discharge in the canal; the membrana tympani less congested and the redness disappearing.

28th. No trouble now with the ear except an occasional tinnitus and no discharge. Hearing distance, Watch $= \frac{18}{48}$. The membrana tympani des-

quamating; still somewhat reddened and slightly retracted. Politzer inflation.

It will be seen from these cases that cold-water bathing may be the cause of only a slight inflammation of the canal or membrana tympani, or the middle ear may be involved, causing perforation of the drum-head, and in some cases leading to mastoid disease. As regards treatment, in severe cases in which the canal or membrana tympani is very much congested and angry-looking, leeching, or, what is better, a small cupping-glass, if applied to the previously scarified parts in front of the tragus, will very often relieve the pain at once, and cut short the inflammation. Aconite should also be given, especially if there is any fever, and the bowels opened by the administration of a saline cathartic. When the mastoid becomes involved, the cupping-glass should be applied over the mastoid process or just below the auricle. Where there is bulging of the drum-head, causing severe pain, paracentesis should be performed. It is surprising how the pain and inflammation in some cases yield immediately to the local abstraction of blood. I prefer wet-cupping to leeching, if the physician can apply the cupping-glass himself, as it is always at hand, the quantity of blood abstracted can be entirely regulated, and it is much more agreeable to the patient. Patients very seldom, if left to themselves, apply leeches properly to parts about the ear.

In mild cases of otitis media, without perforation of the drum-head, attention to the general health and inflation of air by Politzer's method, are frequently all that is required to effect a cure.

In other cases, where the discharge appears, or the membrana tympani is ruptured, or the mastoid becomes involved, the treatment does not differ from that recommended in similar cases from other causes.

MEDICAL PROGRESS.

ON THE TREATMENT OF [illegible] SON, of Copenhagen, gives an account of the treatment lately employed with good results in the Copenhagen Fever Hospital in cases of nasal diphtheria. The serious character of this form of diphtheria having been experienced (the author thinks that the pituitary membrane absorbs the micrococci of diphtheria much more quickly than any other mucous membrane, thus giving rise to serious general symptoms) and the usual treatment, by which either the false membranes were removed with forceps or antiseptic liquids injected in the nose, having proved unsatisfactory in results, or impossible in practice, the treatment by medicated bougies has been adopted. They are made according to the following formula:

Cocain. muriat.	[illegible]
Boric acid	[illegible]
Aq. [illegible]	[illegible]
Gummi arab pulv.	[illegible]
Glycerini	quantum satis.

The length of the bougie for grown-up persons and big children is three and a half inches, the diameter one-fifth of an inch; the same diameter will do for quite small children, the length being only a little shorter, but these bougies contain only $\frac{1}{10}$ grain cocaine (or even less for quite small children) and 10 grains boric acid each. They ought to be stiff and pointed at one end. They are introduced easily and cause hardly any pain or bleeding; one is applied to each inferior meatus, and ought to reach as far as the naso-pharynx. When they are melted, the passage through the nose is often re-established at once, and the mucus and the false membrane are now easily removed by syringing through the nose; but, if necessary, the introduction of the bougies is repeated, one hour being the usual time for them to melt thoroughly. The cocaine acts partly by reducing the swelling, and partly by decreasing the irritation caused by the boric acid, which acts like permanent antiseptic irrigation.—*Journal of Laryngology*, Jan. 1887.

RECENT OBSERVATIONS ON URINE-TESTING.—In an article in the *British Medical Journal* of January 8, 1887, DR. GEORGE JOHNSON speaks as follows, regarding some interesting points in the examination of urine: "My son has been engaged in an elaborate investigation of the reducing agent which is always present in normal urine. The results he will shortly publish in detail. Meanwhile, I may state that he has conclusively proved: 1. That not a trace of glucose is to be found in normal urine; 2. That, as uric acid has no reducing action on picric acid, the chief, if not the sole, constituent of normal urine which reduces picric acid in the presence of potash is kreatinine. He has discovered a simple means of precipitating kreatinine from the urine in combination with a metallic salt, and by a process which has no effect upon any glucose that may be present. A specimen of normal urine which has been thus treated ceases to give the red color when boiled with picric acid and potash, but if, before the separation of the kreatinine, glucose be added to the urine in the proportion of a grain to the ounce, the sugar is found undiminished after the kreatinine has been removed.

"[illegible] —I have often found that the urine of patients who are taking salicylate of soda, when boiled with picric acid and potash, gives a deeper red color than is quite normal, the color being equal to that which would result from the presence of from one to two grains of glucose per ounce. Fehling's solution is also reduced, as it would be by a small amount of glucose. My son has for some time been investigating the nature of this reducing agent. He has ascertained that it is neither glucose nor an excess of kreatinine. It is probably due to some product of metabolism of the salicylate of soda, the precise nature of which remains to be ascertained. The salt itself has no reducing action on either picric acid or cupric oxide.

"[illegible] *Fallacious.*—The Albumen Tests Committee of the Clinical Society, in their report, published in the last volume (xix.) of the *Transactions*, state: 'That a solution of potassio-mercuric iodide with citric acid, particularly when used after Heller's method, gives the most delicate and clearly marked reaction.' It is very noteworthy that the committee make no mention of the fact which has often been recorded, and which must now be pretty generally known, that this test causes an opalescence, not to be distinguished from a slight albuminous precipitate, in every normal urine. This reagent appa-

rently precipitates, not only mucin, but also some other ingredient of normal urine. For it is found that when the mucin in a normal specimen has been precipitated by citric or acetic acid, and then separated by filtration, the addition of the potassio-mercuric iodide to the clear urine causes a further precipitation and opalescence. It is obvious, therefore, that this reagent, if relied upon as a test for a minute trace of albumen, would be seriously misleading."

Potassium Permanganate in Amenorrhœa.—Dr. Marshall, of San Francisco, after employing this drug in fifty cases of amenorrhœa, has arrived at the following conclusions:

1. The permanganate acts satisfactorily in about seventy per cent. of "selected cases."

2. It should be administered one or two hours *after* eating.

The disagreeable action on the stomach may be relieved by combining it with the following:

Oxalate of cerium	1 grain.
Hydrochlorate of cocaine . . .	$\frac{1}{8}$ grain.
Subnitrate of bismuth . . .	5 grains.
Powdered ipecac	$\frac{1}{60}$ grain.

The writer also states that this drug has a marked tonic effect, and generally causes mental exhilaration. —*Canadian Practitioner.*

Management of Simple Constipation.—Sir Andrew Clark gives the following instructions for the management of simple constipation.

1. On first waking in the morning, and also on going to bed at night, sip slowly from a quarter to half a pint of water, cold or hot.

2. On rising, take a cold or tepid sponge bath, followed by a brisk general towelling.

3. Clothe warmly and loosely; see that there is no constriction about the waist.

4. Take three simple but liberal meals daily; and, if desired, and it does not disagree, take also a slice of bread and butter and a cup of tea in the afternoon. When the tea is used it should not be hot or strong, or infused over five minutes. Avoid pickles, spices, curries, salted or otherwise preserved provisions, pies, pastry, cheese, jams, dried fruits, nuts, all coarse, hard, and indigestible foods taken with a view of moving the bowels, strong tea, and much hot liquid of any kind, with meals.

5. Walk at least half an hour twice daily.

6. Avoid sitting and working long in such a position as will compress or constrict the bowels.

7. Solicit the action of the bowels every day after breakfast, and be patient in soliciting. If you fail in procuring relief one day, wait until the following day, when you will renew the solicitation at the appointed time. And if you fail the second day, you may, continuing the daily solicitation, wait until the fourth day, when assistance should be taken. The simplest and best will be a small enema of equal parts of olive oil and water. The action of this injection will be greatly helped by taking it with the hips raised, and by previously anointing the anus and the lower part of the rectum with vaseline or with oil.

8. If by the use of all these means you fail in establishing the habit of daily or of alternate daily action of the bowels, it may be necessary to take artificial help And your object in doing this is not to produce a very copious dejection, or to provoke several smaller actions; your object is to coax or persuade the bowels to act after the manner of nature by the production of a moderate more or less solid formed discharge. Before having recourse to drugs, you may try, on waking in the morning, massage of the abdomen, practised from right to left along the course of the colon; and you may take at the two greater meals of the day a dessertspoonful or more of the best Lucca oil. It is rather a pleasant addition to potatoes or to green vegetables.

9. If the use of drugs is unavoidable, try the aloin pill. Take one half an hour before the last meal of the day, or just so much of one as will suffice to move the bowels in a natural way the next day after breakfast. If it should produce a very copious motion, or several small motions, the pill is not acting aright; only a fourth, or even less, should be taken for a dose. When the right dose has been found it may be taken daily, or on alternate days, until the habit of daily defecation is established. Then the dose of the pill should be slowly diminished, and eventually artificial help should be withdrawn. The aloin pill is thus composed: ℞.—Aloinæ, ½ gr.; extr. nucis vom., ½ gr.; ferri sulph., ½ gr.; pulv. myrrhæ, ½ gr.; saponis, ½ gr.; fiat pil. i. If the feces are dry and hard, and *if there is no special weakness of the heart,* half a grain of ipecacuan may be added to each pill. Should the action of the pill be preceded by griping and the character of the action be unequal, half a grain of fresh extract of belladonna will probably remove these disadvantages. If the aloin pill gripes, provokes the discharge of much mucus, or otherwise disagrees, substitute the fluid extract of cascara sagrada, and take from five to twenty drops in an ounce of water either on retiring to bed or before dinner. And when neither aloin nor cascara agrees, you may succeed by taking before the mid-day meal two or three grains each of dried carbonate of soda and powdered rhubarb.

The exact agent employed for the relief of constipation is of much less importance than its mode of operation. If, whatever the agent may be, it succeeds in producing after the manner of nature one moderate formed stool, it may be, if necessary, continued indefinitely without fear of injurious effects. But, treated upon physiological considerations, I have the belief that in the great majority of cases simple constipation may be successfully overcome without recourse to aperients.—*Lancet,* Jan. 1, 1887.

Diagnosis of Cancer of the Stomach by the Chemical Examination of its Secretions.—Dr. Debove, in the *Gazette Hebdomadaire* of December 31, 1886, reports a case in which the diagnosis of cancer of the stomach was impossible without a chemical examination of its contents.

In cases which were not cancerous hydrochloric and lactic acids or hydrochloric acid alone was found, with very rare exceptions; in cancerous cases it was never detected.

The case reported was that of a man, aged thirty-four, who had suffered from progressive enfeeblement, loss of appetite, and gastric pain for nearly a year. Persistent vomiting of food and mucus occurred later.

On entering the hospital the patient had no tumor, he had never vomited blood or passed blood in his stools; he presented no appearance of especial cachexia.

Washing out the stomach, artificial alimentation, the alkalies in large doses, and strictly regulated diet produced no effect.

Examination of the contents of the stomach showed no hydrochloric acid, but always the presence of lactic acid.

The case was closely watched, and nearly a year after the beginning of his disease a tumor, as large as a small egg, was discovered in the epigastrium, a little to the left of the median line; the diagnosis of cancer was considered assured,

The examination of the contents of the stomach was made as follows: The liquid was filtered as rapidly as possible; in the test for hydrochloric acid gentian-violet (1:5000) gave a blue color in the presence of traces of the acid.

Perchloride of iron gave a yellow color when lactic acid was present; a mixture of three drops of iron and ten drops of a solution of carbolic acid resulted, when added to fluid containing lactic acid, in an amethyst or yellowish-blue color.

BICHLORIDE OF MERCURY SOAP.—GASSELER, of Dresden, has prepared a soap with bichloride of mercury and an excess of fatty acids, which can be kept for a long time, and promises to be very useful, not only in the treatment of skin diseases, but also as a disinfectant.

In the *Med. Forschritt*, JONE has given his results in experiments made with a soap containing 1 per cent. of mercurial. He has seen in anthrax the filaments containing the spores lose their infectious properties in thirty seconds, and bacilli were also destroyed very rapidly. The practical advantages of a disinfectant soap are [illegible]

RECENT MEDICINAL CHEMICALS.—At a recent meeting of the Deutsche Naturforscher und Aerzte at Berlin, Mr. E. Merck exhibited a large number of the products of his chemical works, and published a pamphlet containing notes on some of the more important of them, from which we make the following abstract:

Ethoxy-caffeine.—This compound is produced by substituting the group C_2H_5O in place of one hydrogen in caffeine. It forms white, needle-shaped crystals, melting at 140° C., very little soluble in alcohol or ether, insoluble in water, and of strongly basic properties.

[illegible] considers it a pure narcotic, particularly useful in headache. It is generally administered in solution in water, by the intervention of salicylate of sodium. Dose 4 to 16 grains per day; in single doses of 4 to 8 grains, or in divided doses of 1½ grains.

The same author has also combined it with cocaine as follows:

[illegible]

Salicylate of sodium	[illegible]
Hydrochlorate of cocaine	[illegible]
Linden-flower water	[illegible]
[illegible]	[illegible] fl. oz.

[illegible] this substance (really agaric acid) in relieving the sweating of consumptives has been demonstrated by J. M. Young, Seiffert, and Pröbsting in 1882. It is given in doses of $\frac{1}{12}$ to $\frac{1}{6}$ grain in pills, to which some Dover's powder is usually added, since agaricin often produces loose bowels, sometimes accompanied by violent abdominal pains. Young recommends the following combination:

℞.—Agaricini	[illegible] gr.
Pulv. ipecac. et opii	[illegible] gr.
Altheæ pulv.,	
Mucilag. acaciæ	. āā 60 gr.

To be made into 100 pills; 1 or 2 pills to be taken at night.

The hypodermatic administration of agaricin causes pain.

Considerable quantities of Merck's agaricin have been used in Bellevue Hospital for relieving the night-sweats of consumptives, or other patients suffering from the same cause, with uniform success. It is usually given in combination with atropine and aromatic sulphuric acid:

℞.—Agaricini (Merck)	10 gr.
Atropinæ sulphatis	1 gr.
Acid. sulph. arom.	[illegible] m.

Dissolve and filter. *Dose:* 10 minims, containing $\frac{1}{10}$ grain of agaricin, $\frac{1}{120}$ grain of atropine sulphate, and 10 minims of aromatic sulphuric acid. To be administered in syrup or simple elixir.

Aloin.—Merck's aloin is "barbaloin"—that is, it is the aloin extracted from Barbadoes aloes.

May be used in doses of 2 to 4 grains.

Codeine Phosphate.—The introduction of this salt has rendered the hypodermatic use of the alkaloid possible. It is recommended highly in diabetes, in doses of 1 grain three times daily, increasing every week by 1 grain, until about 9 grains are reached. Cod-liver oil should be given at the same time (Smith; Hermann). In morphinism, Leppmann recommends the alternate administration of one-third to seven-eighths grain of this salt, and eight grains of monobromated camphor.

Colchicin.—The pure crystallized principle is a powerful poison and must be used with caution. The dose, in gout and rheumatism, is $\frac{1}{120}$ to $\frac{1}{30}$ grain two or three times daily. Not to be recommended for subcutaneous use.

Colocynthin, the glucoside of colocynth, is soluble in water and alcohol. When administered internally, or *subcutaneously*, it acts as a purgative, but the hypodermatic employment is painful. Injected into the rectum it causes purging within one hour. Dose, internally, 1½ to 6 grains; hypodermatically, $\frac{1}{16}$ to $\frac{1}{4}$ grain, dissolved in water. Possibly, when combined with cocaine, the hypodermatic injection may be rendered painless. It would be very advantageous if it could be used in this way, as there are many cases where it would be desirable to be able to administer a purgative hypodermatically.—[illegible]

COCAINE IN SEA-SICKNESS.—OTTO has treated this most disagreeable of maladies by an aqueous solution of hydrochlorate of cocaine, 1 to 10, of which five drops are given three or four times daily on a bit of ice.—*Gazette Hebdomadaire*, December 17, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE $7.00

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 29, 1887.

OSTEOPLASTIC RESECTION OF THE FOOT.

AMONG the operations of excision at the ankle-joint, one of the most ingenious is that which was first practised in 1871, by WLADIMIROFF, and brought into general use ten years later by MIKULICZ, who made certain improvements in its technique. This operation was called "artificial pes equinus," by Wladimiroff, and "osteoplastic resection of the foot," by Mikulicz. The former of these names indicates the result of the operation; the latter, rather vaguely indicates its character. It consists essentially in a resection of the lower ends of the tibia and fibula with the whole of the astragalus and calcaneum, and the posterior portion of the cuboid and scaphoid bones, followed by placing the cut surfaces of the scaphoid and cuboid bones in contact with those of the tibia and fibula, and closure of the wound. HABERERN proposed suturing the approximated bones, in order to secure better union, and this suggestion was carried out by SKLIFOSSOWSKY in 1882, and by FISCHER in 1884.

The incisions practised by Wladimiroff differ somewhat from those used and recommended by Mikulicz, which have been judged to be an improvement upon those proposed by the originator of the operation. In Mikulicz's operation the patient is placed prone upon the abdomen, and an incision is carried across the sole of the foot to the bones, from the tubercle of the scaphoid to just behind the base of the fifth metatarsal bone. From each end of this incision another is carried upward to the corresponding malleolus, and between the upper ends of these a fourth incision is carried across the back of the ankle joint, dividing the tendo Achillis. The ankle-joint is next opened and the astragalus and calcaneum dissected out from behind. The lower ends of the tibia and fibula and the posterior surfaces of the scaphoid and cuboid bones are then sawn off, the foot is placed in a position of pes equinus, with the cut bone surfaces in contact; and the wound is closed. Sutures or pegs may be used to fix the bones in contact, or they may not, as the operator thinks best. In the cases in which this last step has been taken the results have not been any better than in those in which it has been omitted, although theoretically there can be no question that it is a proper one.

This operation comes into rivalry chiefly with the amputations of Syme and of Pirogoff, when the latter seem to be indicated in cases of serious injury, or of caries of the astragalus and calcaneum. Mikulicz did his first operation in 1880 for an intractable syphilitic ulcer of the foot; Remsen did one in 1884 for deformity after a complicated and neglected fracture at the lower end of the leg; Niehans operated in 1884 (?) for an injury of the ankle. All the other operations, to the records of which we have access, were done for caries.

In a recent paper in the *Archiv für klinische Chirurgie*, Bd. xxxiii. Heft 3, 1886, ZESAS has collated the statistics of nineteen operations by the method of Wladimiroff or of Mikulicz, in all of which, with one exception, the functional result was excellent. In one case gangrene of the foot followed the operation, and it was necessary to amputate in the lower third of the leg. Out of sixteen cases operated upon for caries, speedy recurrence is noted in four; so that the hope that this operation would furnish a better protection than a less radical one has not been fulfilled so far.

The special merit of Mikulicz's operation consists in the functional result, which is better than that following a Syme's or a Pirogoff's amputation. Perhaps it might be better still if care were taken to spare the tendon of the peroneus longus muscle and if the tendo Achillis were sutured to the periosteum of the scaphoid and cuboid bones. This, so far as we know, has never been attempted, and it might prove more difficult in practice than it seems to be in theory. Nevertheless, we offer the suggestion for the consideration of those who may hereafter undertake the Wladimiroff-Mikulicz operation.

RECTAL INJECTIONS OF GAS.

THE treatment of chronic pulmonary diseases is of daily interest to the practitioner, who welcomes eagerly new methods which hold out a hope of relief to troublesome symptoms, or of cure in a long standing and obstinate case. New remedies, like new servants, seem always to do well at first, but, with the one as with the other, it takes time before the good and bad qualities can be discovered. A

few years ago we were using respirators and inhalers in the treatment of phthisis and chronic bronchial troubles, and the journals were filled with reports of wonderful results obtained by this method. Ask the nearest pharmacist and he will tell you that now the sales of respirators in a year are not equal to what they were in a week, and that practically the method has been abandoned. Meanwhile the fight goes bravely on, and as the enemy has not yielded to the attack *a fronte*, the tactics have changed, and we are asked to assault him *a tergo*.

It has long been known that an interchange takes place between the gases of the blood in the intestinal capillaries and those contained in the bowel. Some time ago BERNARD and CORNIL called the attention of the French Academy to the fact that gases injected into the bowel pass to the lung and are exhaled. Relying upon this physiological fact, BERGERON, of Lyons, and several other French therapeutists have advocated the treatment of chronic pulmonary diseases by the rectal injection of gases. Already the reports of the success in chronic bronchitis, asthma, and phthisis, are so favorable that the method is likely to come into very general use, and we may soon expect here to have a Wolff's bottle by the side of each phthisical patient, who will take his medicine thrice daily through a rubber tube and a rectal canula. Indeed, the plan has been for some time in use at the Philadelphia Hospital.

At the Société de Thérapeutique there has recently been a discussion on the subject, and from the report in the *Gazette Hebdomadaire*, No. 51, 1886, we glean the following information. DUJARDIN-BEAUMETZ stated that he had twenty-five patients under the treatment, and preferred the sulphuretted hydrogen to the carbonic acid, or to the sulphuretted or carbonated waters. The carbonic acid alone always caused colic without any improvement, but the addition of sulphuretted hydrogen caused a diminution of the cough and of the expectoration, while the sleep returned and the appetite improved. These good effects were not always obtained until after treatment had been employed for some time. He had also used eucalyptus and iodoform, but without benefit. In bronchial catarrh the improvement was in some cases most marked and rapid. PAUL recommended a sulphur water charged under pressure with carbonic acid. In siphons this is readily available, and the gas is allowed to enter the bowel until there is a feeling of tension and heat, and a tendency to expel the canula. About one quart of gas is injected at each sitting; as much as two quarts usually causes dilatation of the transverse colon and painful tympany.

The general opinion seemed favorable to a further trial of the method. It was remarked that the patients [illegible] under this plan of treatment, and they were not satisfied with the injections alone.

FATAL POISONING BY WATER-GAS.

THE Troy cases of poisoning by the inhalation of water-gas are likely to attract widespread attention because of the recent largely extended use throughout the United States of this gas for fuel and illuminating purposes, and we are fortunate in being able in this issue to lay before our readers Dr. Bontecou's report of their medical history.

The danger of water-gas is greatly increased by reason of its having no perceptible odor, and the Troy catastrophe shows that while a house may be unconnected with the gas mains its occupants may not be secure from its poisonous influence, and that, while ignorant that they are inhaling it, they may gradually and unconsciously pass into a narcotic sleep from which they may never awake.

The liability to the leakage of gas from the mains, and its filtration through the soil into houses, is increased in winter by the more frequent breakage of pipes, and also, perhaps, by the closing of windows and the artificial heating of rooms, incident to that season, which invite the entrance and accumulation of the escaping gas.

The inhalation of water-gas proves poisonous through the presence of carbonic oxide. The symptoms noticed are dizziness, faintness, severe headache, with sense of constriction, epigastric pain, vomiting, stupefaction, and, finally, coma and death. The chances of recovery decrease in proportion to the length of time the gas has been inhaled, and the blood has become saturated with it.

The practical lesson to be learned wherever water-gas is used, is that on the earliest occurrence of any one of these symptoms of poisoning the atmosphere of the room should be thoroughly changed immediately by opening the windows, and if on their closure these symptoms reappear, it may be reasonably suspected that there is an escape of gas in or near the house. When the symptoms of narcotic poisoning are established, cold affusions, stimulants, venesection, and artificial respiration are demanded, in addition. In cases in which the exposure to the gas has continued for some hours, and coma is pronounced, these measures are likely to prove unavailing, and transfusion, or refusion should, also, be employed. This latter measure, which consists in withdrawing the poisoned blood, oxygenating and defibrinating it, and then returning it to the circulation, has given, in some cases, encouraging results, as shown by Dr. Halsted, in a valuable paper which appeared in THE MEDICAL NEWS of Dec. 8, 1883.

We are glad to learn that the manufacture of this gas has been suspended at Troy until some method

can be devised to give to it an odor by which its presence may be detected, and it may thus be robbed of its greatest danger.

A REMARKABLE OUTBREAK OF TYPHOID FEVER.

BROUARDEL has communicated to the Academy of Sciences the details of a localized outbreak of typhoid fever in which it is claimed that the specific bacillus was found in the contaminated water.

The facts, as given in the *Gazette Hebdomadaire*, No. 51, 1886, are briefly as follows: During the months of August and September, twenty-three persons had occupied three contiguous houses at Pierrefonds, of whom twenty were attacked with typhoid fever. Four members of one family died. Insanitary conditions of the most aggravated kind existed. The water supply was from shallow wells filled by percolation from a neighboring stream; one cesspool was situated at a distance of thirty feet from a well, the other at a distance of sixty-five feet. The soil was light and porous, and the level of the water was below that of the cesspools. The interesting feature of the investigation was the detection, by Chautemesse, Director of the Bacteriological Laboratory of the College of France, of the bacilli regarded as the specific agent of typhoid fever. On October 18th they were present in large numbers in the water supplied to the house in which the four deaths had occurred. On October 29th there were fewer, and on November 21st none could be found. In the other wells similar organisms did not exist.

To demonstrate the identity of the bacilli found in the water with those of the typhoid patients, the spleen of one was punctured with a sterilized trocar on the tenth day of the illness, and in cultures of the material colonies developed in the same morphological and biological characters as those obtained from the well water. The coloration and sporulation of the bacilli were identical.

This is not the first time that the typhoid bacillus has been found in drinking water, but we do not know of an instance in which the details have been so carefully worked out as in the Pierrefonds epidemic.

EXPERT FEES IN OHIO.

IT is likely that the question of special compensation for expert testimony will soon be brought to an issue before the courts of Ohio, ultimately even before the Supreme Court itself, through Dr. F. H. Darby, of Morrow, who was recently summoned by the State as an expert in a murder case. He refused to answer the following question unless paid a fee as an expert: "State whether in wounds like this there would be immediate gaping, or would the lips of the wound for a time remain in contact or nearly so?" The judge declined to grant the fee asked, because he held that there was no law for it, and Dr. Darby, for his refusal to reply, was sent to jail for contempt, and he was only released, after several days' confinement, on his own recognizance. We understand his case will be made a test one.

Dr. Darby based his refusal on the ground that he was asked to give expert testimony, and, as it was not claimed that he had any personal knowledge of the case, the issue is a square one. In some similar cases which have been decided in other States, the physician was a witness as to facts, and refused to answer when questioned as to matters of opinion. In several such cases the Court has not sustained the physician, refusing to discriminate between a pure question of fact and an incidental one of theory.

In the State of Iowa the law reads that "Witnesses called to testify only to an opinion founded on special study or experience in any branch of science, or to make scientific or professional examinations, and state the results thereof, shall receive additional compensation, to be fixed by the Court, with reference to the value of the time employed, and the degree of learning or skill required." North Carolina, Rhode Island, and Minnesota have similar laws.

The sympathies of the profession are with Dr. Darby in the important stand he has taken, and we hope that he may receive material aid in its prosecution, and that his case will reach a favorable decision.

THE DEATH OF EDWARD LIVINGSTON YOUMANS, M.D., in New York City, on January 18th, occurred from pulmonary tuberculosis, supervening upon a severe pneumonia of two years ago. He was born in 1821, and graduated in medicine at the University of Vermont. He never followed medicine as a profession, but adopted that of a lecturer upon scientific subjects, and became the author of numerous books on those subjects. His name was widely known as the editor of the *Popular Science Monthly*, with which journal he was identified from its inception in 1871.

DR. WILLIAM STEVENSON ROBERTSON died at his birth-place, Muscatine, Iowa, on January 20th, aged fifty-six years. He was President of the Iowa State Board of Health, and Professor of the Theory and Practice of Medicine in the Iowa State University.

WE have upon several occasions, in giving the statistics of ovariotomy in Italy, referred to the work of Prof. d'Antona, of Naples, who now probably stands, in number of cases, at the head of the ovariotomists in that country. Of 48 completed and reported ovariotomies, up to 1885, for the removal of single and double cystomata, but 7 had

resulted fatally, and by his last report of 13 cases, there was no death. From a tabular record prepared in September, 1886, we learn, that he has performed the following operations, with their appended results.

Freund's method	
Vaginal hysterectomy for cancer	
Supravaginal hysterectomy for cancer	
Myotomy for myofibromata, "per uterine and broad ligament"	
Laparotomy for removal of "epiploic	
Laparotomy for removal of subperitoneal	
Nephrolithotomy	

The Medical Society of King's County, N. Y., held its annual meeting at Brooklyn, on January 16, 1887, and elected the following officers for the ensuing year:

President.—William W. Faser, M.D.
Vice-President.—A. Ross Matheson, M.D.
Secretary.—C. Delavergne, M.D.
Treasurer.—W. B. Chase, M.D.
Librarian.—J. H. Hunt, M.D.

Barker's work on *Puerperal Diseases* and Emmet's *Gynecology* have recently been translated into German and published by Abel, of Leipzig.

Professor Ludwig Bandl died during the first week of December, 1886, at Prague, where he had taken the Chair of Obstetrics and Gynecology made vacant by Breisky during the past summer. Graduated in 1867 at Vienna, he had been private docent, instructor in the Vienna Polyclinic, and Professor (extraordinary) of Gynecology in the University of Vienna. His writings upon *Rupture of the Uterus, and Its Mechanism*, and his article upon "The Diseases of the Tubes, of the Ligaments, of the Pelvic Peritoneum, and the Pelvic Cellular Tissue, including Extrauterine Pregnancy," in Billroth's *Hand book on the Diseases of Women*, have made his name familiar. He was a popular and earnest teacher, and his studies regarding the uterine contraction-ring, which has borne his name, have excited much discussion among obstetricians.

The Central Texas Medical Association recently held its second quarterly meeting, at which the President, Dr. F. M. Pitts, delivered an address, and Drs. W. L. Barber and H. W. Dudley read papers on typho-ma arial fever.

Owing to the fact that the American Medical Association will hold its annual meeting in Chicago, on June 7th to 10th next, thus conflicting with the date for the annual meeting of the Michigan State Medical Society, the Executive Committee have designated the 12th and 13th day of May next for the annual meeting of the State Medical Society.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, January 3, 1887.

The President, B. F. Baer, M.D., in the Chair.

Dr. Wm. Goodell read a paper entitled,

A YEAR'S WORK IN OVARIOTOMY.

(See page 119.)

Dr. Parish cited a few instances of evil results following abdominal tapping for purposes of diagnosis or for relief from distention. In his first ovariotomy case, with the view of clinching the diagnosis, he aspirated and withdrew a few drachms of somewhat cloudy ovarian fluid. The patient presented some symptoms which in a few days became grave; pain in the tumor, rigors, rapid and feeble pulse, and high temperature. He operated during the existence of these symptoms, and found suppuration of the interior of the cyst and extensive anterior adhesions; both conditions doubtless dependent upon the aspiration; the patient recovered.

A few years ago a well-known medical gentleman of this city aspirated a tumor supposed to be a multilocular ovarian cyst. Though the fluid was stated to verify the diagnosis, the patient miscarried in one or two days of twins at about the fifth month, and the tumor proved to be simply a uterus enlarged by means of a multiple pregnancy. He recently saw in the Philadelphia Hospital a shocking case of labor, in which active labor pains began one week previous to her admission to the hospital. No urine had been voided for several days. Pregnancy was denied by the patient and her friends, and was not recognized by two physicians. The woman was small and deformed, and in the abdomen were two fluctuating tumors, one due to a distended bladder, the other the uterus. Aspiration was resorted to in both tumors, a procedure that was not only unnecessary for diagnostic purposes in this case, but which would probably have been highly detrimental to the patient, had not the neglected and protracted labor already determined a rapidly fatal result. Though tapping for relief and especially for diagnosis is less frequently resorted to than was the case a few years ago, yet even now it is too frequently done.

In reference to the development of cancer or sarcoma, after the removal of seemingly benign ovarian tumors, he recently saw an example in a patient operated on by Dr. Hickman and himself. A large cyst of one ovary and a small one of the other, both free from the appearance of malignancy, were removed,

and the patient made a tardy recovery. In about a year sarcomatous growths developed in the neck and axilla, and a large one in the abdominal wall of the left lumbar region. The patient died a few weeks ago, and the autopsy was made by Dr. Morris Longstreth; and though the sarcomas referred to were present, there was no intrapelvic disease. An interesting feature was the total disappearance of the ligature of iron-dyed-silk with which the pedicles and several vessels were secured about eighteen months previously.

Dr. H. A. Kelly stated that while simple tapping was often in no way injurious, it was also often productive of grave injury, and one of his own cases illustrated this point very well. The patient having a cyst weighing 100 pounds, was tapped in the left iliac region by a notorious homœopathic surgeon. She had previously suffered from pressure symptoms. From now on she suffered from severe inflammatory pains around the puncture, and at the operation the extensive dense adhesions at this point constituted the chief difficulty. She is now well, more than a year since the operation. It is a cause for mutual congratulation for American operators, that their results are becoming so good. The whole credit of this lies in the thorough use of antiseptic agents and the rendering the field of operation completely *aseptic*.

He believes, too, that our cases are more difficult than those being operated on abroad. The tumors we operate upon are older, and with the increasing age of an ovarian tumor occur many changes detrimental to the patient, depression of vitality from pressure symptoms, diversion of so much albumen from the system at large, surcharge of the emunctories, as well as adhesions and unfavorable changes within the tumor itself. Keith's dressing of a strongly carbolized glycerine has rendered excellent results in Dr. Kelly's hands in at least twenty cases.

Dr. Goodell, in answer to a question by Dr. Baer, said he operated during menstruation merely from pressure of time on the part of the patient, and little or no effect was produced on the discharge by the operation.

Dr. Joseph Price, in commenting upon some points alluded to in Dr. Goodell's paper fearing the contaminated atmosphere of a general hospital, cited the statistics of two hospitals: Special Department of Birmingham General Hospital and Birmingham Hospital for Women, covering a period from Jan. 1878, to Sept. 1885.

Special Department of General Hospital, ovariotomy 35 cases, 11 deaths; mortality, 31.4 per cent.

Birmingham Hospital for Women, ovariotomy 268 cases, 19 deaths; mortality, 7.1 per cent.

During the same period the total number of intra-abdominal operations in the Special Department of General Hospital, 85 cases, with 21 deaths; mortality, 24.7 per cent.

Birmingham Hospital for Women, 632 cases with 49 deaths; mortality, 7.7 per cent.

One point as to the value of the spray, quoting from Keith's report of cases treated in the Royal Infirmary, Edinburgh.

Carbolic acid spray cases:

Ovariotomy, 21 cases: 18 cured, 5 died.

Hysterectomy for fibroid, 2 cases: 2 cured.

Battey's operation, 1 case: 1 died.

24 cases with 4 deaths; mortality, 16.66 per cent.

Boro-glyceride spray cases:

Double ovariotomy, with hysterectomy, 1 case died.

Hysterectomy for fibroid, 1 case recovered.

Result with boro-glyceride spray, 2 cases with 1 death.

No spray:

Ovariotomy, 47 cases: 46 cured, 1 died.

Hysterectomy for fibroid, 7 cases: 7 cured.

Battey for fibroid, 1 case, cured.

Interstitial pregnancy, 1 case, cured.

56 cases with 1 death.

Mr. Keith says: "No cases of serous cysts of the broad ligament were operated on. These all were treated by tapping, and none of them have returned." One such case that Dr. Price saw died a few days later. Of Dr. Keith's cases, one-half had no adhesions.

Dr. Montgomery considered Dr. Goodell's success gratifying, especially after tapping. A patient came to him one month after tapping. She had a high pulse, septicæmia, large adhesions to viscera, etc., putrid clots in the tumor, and died on the fifth day with a temperature of 105°. He does not approve of tapping broad ligament cysts. One patient with such a tumor was tapped seven times. He afterward removed the tumor, and did not have a single vessel to tie. In this case, the peritoneum had been pushed up by the tumor, and was not opened until late in the operation.

Dr. Goodell made a few remarks on the subject of statistics. Dr. Keith's have improved, not because he has given up the spray, but because he has grown to his work. Dr. Goodell will give up the spray because it is an intolerable nuisance. As to the question of malignancy of ovarian tumors, it has been said that "all ovarian tumors are malignant, and should be so treated." This is too sweeping; but the tumors should in all cases be removed as soon as discovered.

Dr. R. P. Harris desired Dr. Parish to report the present condition of the patient from whom he had removed the ovarian tumor exhibited by him before the Society, at its meeting on March 4, 1886, the day after the operation. Dr. Parish had requested Dr. Harris, who had seen her much more recently than he had, to report her condition. Dr. Harris stated that notwithstanding the fact that the tumor was largely solid, that it had grown rapidly, that the solid portion had an appearance of malignancy, and that there was a small morbid growth projecting upward from the fundus uteri, the lady was to all appearance a well woman. He saw her on December 26, when she claimed to have perfectly recovered her health and strength after a very prolonged convalescence. Her appearance and activity certainly indicated that her statement was correct. The uterine nodule must have been a fibroid, as, had it been cancerous, it must have materially developed in nine months. The future of this case will be of much interest.

Dr. Charles Meigs Wilson reported

THREE SUCCESSFUL TAIT OPERATIONS.

These cases are the first of a series performed without the use of carbolic acid solutions for instruments, and without the spray. Hydrant water, boiled for six hours, was used for the instruments and sponges in the first and second cases, and a solution of mercuric chloride, 1 to 5000, for like purposes in the third. The wounds in all three were dressed after the manner of Keith.

The incisions were less than two inches in length. More than three months has elapsed since the operation in each case before it has been reported. It has seemed best to publish the cases in this manner, because the vast majority of all cases recover without accident from the operation, and hence mere statistics of the healing of the wound amounts to little but evidence of individual skill. Statistics of the real relief afforded by the operation are what the profession needs in order to give the operation its just place in modern surgical procedures.

[illegible] case first came under observation in July, 1886. She gave her history as follows: Miss McM., æt. thirty-two, nullipara. For the last sixteen months has had a rapidly growing tumor of the abdomen; menses profuse; catamenial intervals ten to fifteen days; for the past four months has rarely been free from bloody vaginal discharge. She was emaciated, anæmic, and alarmed about the constant bloody discharge. She had reflex pains, but no ovarian tenderness or pain. She was obstinately constipated, owing to the pressure of the tumor upon the rectum. She was found to have a large fibroid tumor of the fundus and anterior wall of the uterus. The enlarged uterus was incarcerated in the cavity of the pelvis and was very immobile. The sound entered the uterus seven and a quarter inches. Abdominal section was performed, September 20, 1886, with the assistance of Drs. E. Wilson, C. P. Noble, and D. Longaker. The tubes were as thick as the finger, they had thin walls, and were distended with blood. The ovaries were oversize, and the right one was cystic. The ligature slipped from the uterine end of the left tube, and before it could be secured there was free hemorrhage. The operation lasted forty minutes. Convalescence was retarded by abscess of one of the suture tracts. The patient made an excellent recovery. Present condition: Has lost no blood since the second day after the operation; appetite good, and is able to resume her occupation of seamstress; frequently walks two miles to her work: all pain has disappeared; has gained twenty-two pounds since the operation, December 20th. The sound entered the uterus three and a quarter inches; the tumor was greatly reduced in size.

Case II. Hystero-epilepsy.—Mrs. C., æt. thirty, primipara. Had always enjoyed good health until after the birth of her child, six years ago. She had been delivered with forceps, and the cervix and perineum had been badly torn. She was in bed nine weeks after the confinement. No clear history of her puerperal trouble could be obtained. She has had profuse catamenial discharges since. About six months after the birth of her child, she first commenced to have attacks of loss of consciousness, followed by epileptiform seizures at her menstrual periods. These gradually became so violent as to place her life in seeming jeopardy during their occurrence, and left her utterly prostrated. She had been in bed about twenty days out of every month for four years. Her epileptic seizures occured only at her monthly periods. Everything that her medical attendant could think of had been done for her, and her family were about to place her in an insane asylum. The ovaries and tubes were removed October 3, 1886. The operation was an easy and simple one. The patient made a speedy recovery without any untoward symptoms. Present condition: She is now able to earn her living as a yarn picker, working full time; has had no discharge of blood; little or no pain; *and not one* [illegible]

Case III. Tubercular pyosalpinx.—Miss E. R., æt. nineteen, nullipara. This patient was also operated upon on October 3, 1886. Since menstruation began, at fifteen years of age, she has had constant, dull, aching pain, deep seated in the pelvis. At her menstrual epochs "her agony has been unbearable." Menses have always been slight in quantity and regular as to time. She presented a badly nourished appearance. Physical examination showed marked evidence of general tuberculosis. In spite of this fact, and in view of her intense menstrual pain, oöphorectomy was deemed justifiable and was accordingly done. Both tubes were of the size of large Bologna sausages, and both ovaries were cystic. Tubes and ovaries were matted in a mass of adhesions, which rendered the operation very tedious, it lasting one hour and ten minutes. Microscopic examination of sections of the tubes showed colonies of the Bacillus tuberculosis. Both tubes were filled with a greenish pus which was very offensive. The recovery was complicated by an arthritis, the symptoms of which were so obscure as to render it difficult to say whether it was septic, rheumatoid, or hysterical. She eventually made a good recovery. Present condition: Her physician, Dr. Walter E. Bibby, of Kensington, Philadelphia, reports: "She is entirely free from pain; able to walk about, and to attend to light household duties. Under the use of cod-liver oil, malt, and alcohol her tubercular trouble seems to be making little or no progress." As her peritoneum showed evidence of tuberculosis, as an experiment, bichloride solution, 1 to 8000, was used to wash out the abdominal cavity.

In each case the abdominal cavity was thoroughly flooded with boiled water before it was closed. The drainage tube was not used. Uncarbolized Chinese silk ligatures and silkworm-gut sutures were used. No anodyne was given after the operation, and no food was given for thirty-six hours after operation.

Dr. H. A. Kelly was particularly interested in the tuberculous tubes, and regretted that an examination of the uterine discharges had not been made, as it would almost certainly have established the diagnosis. As to the right to operate upon a patient having a cavity in the lung, no general rule can be laid down; every such case stands by itself, and much must be left to the judgment of the operator.

Dr. Baer would hesitate for some time before operating in a case of general tuberculosis with a pulmonary cavity. He did not think tuberculosis could cause pyosalpingitis.

Dr. Kelly remarked that at least two cases have been observed here and many more abroad, and it has been recently formulated by Prof. Hegar among the tubal diseases which may require operation.

Dr. Parish thought the general condition of the patient outside of the pulmonary disease should decide the question. Severe pain should be relieved, unless the patient had a very short time to live.

HYDROSALPINX.

Dr. H. A. Kelly exhibited the tubes of a patient who had suffered from metrorrhagia over thirteen years.

She had been in five large hospitals in Philadelphia, without relief, and had faithfully tried every plan of treatment, systemic and per vaginam. The diagnosis of enlarged tubes was made before operation, and on removal with their respective ovaries, the tubes were found, one as large as a Bologna sausage, and the other a small sausage, with a limpid fluid. She has lost no blood since the metrostaxis following the operation, about six weeks ago.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 20, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. J. H. RIPLEY read a paper on

THE VALUE OF QUININE AS AN ANTIPYRETIC IN PNEUMONIA.

The experiments on which his observations were based were commenced in 1877, at St. Francis's Hospital, New York, and since that time had been continued by successive house physicians acting under his direction. Although a much larger number were made, the experiments available for the purpose under consideration were 48 in number, and the patients who were the subjects of these, varied from 19 to 45 years of age. The plan carried out was to give quinine as early as possible in the course of the disease; but only in cases in which the temperature was at least 103°, and which were uncomplicated. Each patient was watched for several hours before the experiment was commenced, and all the observations of temperature were taken in the rectum. No experiment lasted less than four hours, and the majority were continued for from 12 to 15 hours. The time of day at which the quinine was administered varied; but when only a single dose was given in the twenty-four hours it was given in the morning. In 20 of the experiments a single dose of 20 grains was given, and in 8 a single dose of 40 grains. It was usually given in solution, but in some instances was used hypodermatically. In two of the patients there was no reduction of temperature whatever noted after the use of quinine, and in two a slight elevation occurred. The reduction of temperature effected by the quinine was always of short duration, and it was frequently less than an hour. The effect of the remedy on the pulse and respiration was not a constant guide to its effect on the temperature. It varied in different cases, bu ıe pulse and temperature were usually reduced in frequency.

In about half the cases the temperature was lowered between one and two degrees under the use of quinine. In the other half, the reduction was less than half a degree. The gain thus made was never held for more than from two to four hours. In many cases the antipyretic effect was, no doubt, only apparent, and the reduced temperature was really due to natural causes.

The conclusion arrived at by Dr. Ripley was, that quinine is a feeble and uncertain antipyretic in pneumonia. But this is not all. It has a bad effect on the appetite and digestion, and not infrequently excites nausea and vomiting. In addition, it is liable to produce marked cardiac weakness, profuse cold perspiration, and profound nervous depression. Opisthotonos was noticed in one instance, and in many cases it caused epistaxis. In three cases the urine was examined before and after the ingestion of quinine in large doses; and in one, the urine, previously normal, was found to contain large quantities of albumen, hyaline casts, and renal mucus after the use of the drug. These bad effects, he thought, more than counterbalanced any good effects that could be attributed to it.

Moreover, he could not see that it had shortened the natural course of the disease in any case. In some instances the pneumonic consolidation had extended under its use. In general, he believed, that too much importance is, at the present day, attached to the reduction of temperature in febrile diseases. In typhoid and other fevers much better results had been obtained at St. Francis's Hospital since heroic measures for reducing temperature had been given up. That quinine has any effect in preventing cell migration, as alleged by certain authors, he thought was extremely doubtful. In conclusion, he expressed the opinion that large doses of quinine in pneumonia should be abandoned. If an antipyretic effect were desired, we possess much more efficient agents in antipyrin and salicylate of sodium.

DR. PUTNAM JACOBI said that of 100 cases of pneumonia in children of which she had notes, 59 were available for statistical purposes. In these the average age was two and a half years, and 7 deaths were known to have occurred. She spoke of the effect of quinine on the physical signs and on the fever, and said that no decisive results could be gathered from the cases. Five grains, night and morning, seemed as efficient as larger doses in children. The conclusion that she arrived at was that quinine is not to be relied upon as an antipyretic, and that it is an efficient remedy in the pneumonias of children only so far as it affects the morbid process present. It tends, she thinks, to limit the secondary extension of the disease.

DR. J. LEWIS SMITH said that as Dr. Jacobi's cases occurred in the out-door department of the Mount Sinai Hospital, it could not be known whether the quinine was vomited or not. This drug is exceedingly liable to excite nausea in children, and the best way that he had found to administer it was in connection with wild cherry bark. He was in the habit of administering one large dose with a view to preventing cell migration; after which he preferred to give it in doses of from one to one and a half grains every four hours. It is a useful tonic, and he thinks that it prevents secondary lesions.

DR. FRUITNIGHT said that the common practice had been to give quinine for almost everything; but since the introduction of other antipyretics he thought the tendency has been to discard this agent to a large extent. The reaction was like the swinging back of the pendulum, and he believed it the part of prudence to pursue a middle course. His experience with quinine as an antipyretic in pneumonia coincided with that of Dr. Ripley; but at the same time he intends to continue to use the drug in this disease, not for its antipyretic, but for its sustaining effect. To secure this it should be given in small doses. One great danger in pneumonia is cardiac failure, and in large doses quinine is supposed to have a tendency to produce

this. In small doses, however, no such effect is observed.

Dr. F. A. Castle said that his experience fully bore out that of Dr. Ripley as to the uselessness of quinine in pneumonia. Ten years ago Beriz recommended it in large doses, giving as much as seventy grains in the twenty-four hours. Personally he had never carried it to this extent, but he had used it in as large quantities as the stomach would bear. He had found, however, that if the temperature was to be reduced by quinine, it must be at the expense of the nutrition of the patient. In the broncho-pneumonia of children, if carried beyond tonic doses, it had a bad effect on the stomach, and also tended to produce delirium. For the last five years he had almost entirely abandoned this remedy in pneumonia. As regards sustaining the heart, he thought we have a much more reliable agent than quinine in digitalis.

Dr. C. F. Billington said that, like Dr. J. Lewis Smith, he had found quinine very apt to produce vomiting in children, and he had, therefore, found great satisfaction in giving it in the form of a suppository. In case any rectal or anal irritation is caused by this method, it can easily be entirely avoided by the use of a simple apparatus provided with a piston-rod, which can now be obtained for the purpose. By employing this the administration can be kept up for any length of time desired without the slightest inconvenience. He, therefore, considered the method of giving quinine by the rectum one of great practical value. In pneumonia he had been disappointed in quinine as an antipyretic, and he had also found that its use is attended with other bad results. In children the natural tendency is to recover, both in broncho-pneumonia and in ordinary pneumonia, and a large number of cases get well without any treatment at all.

Dr. L. Emmett Holt said that of twenty cases of pneumonia in children treated by him with quinine or cinchonidia, in twelve the drug was given in sufficient doses and for a sufficient length of time to enable him to form some opinion of its action, and in nine it was a total failure so far as any effect upon the temperature was produced. He gave as much as sixteen to thirty grains a day to children from one to two and a half years old, and in two or three cases the temperature rose steadily after the quinine had been taken. He said that his own feeling was that, given in small doses it is useless as an antipyretic, and given in large ones it is dangerous. In high fever he had met with much better results from the judicious and continued use of the cold pack, and by this means he had been able to save some cases which were to all appearances entirely hopeless. In general, he was doubtful about the value of antipyretic treatment in pneumonia, unless the temperature were unusually high. For the past two years he had abandoned the use of quinine entirely in pneumonia, as a rule, as he found that it almost always produced vomiting or other bad results; and he had obtained as good, and better results, since he had given it up. It was, however, of very decided advantage in convalescence, and in protracted cases of broncho-pneumonia, if given in small doses.

The President said that he had seen some marked changes in opinion in regard to quinine in New York during the last thirty years. At one time much was expected from the administration of half a grain to a grain a few times a day to adults, and of even smaller doses to children. It was true that a larger number of cases got well, but they were the kind of cases in which the natural tendency is to recovery. It is only in bad cases that we can really judge of the effect of any remedy. At that time he said he had gained a very great reputation for over-dosing by giving six, eight, ten, and twelve grains of quinine to children. Since then professional opinion had entirely changed, but he still adhered to the practice. He laid stress on the desirability of giving the drug at certain times of the day. It should usually be given in the morning, when the intermission occurred, and full doses might be given in two portions: say five grains at 8 o'clock, and five grains at 11 o'clock. If it did not produce an unpleasant effect upon the stomach, he would recommend that one full dose should be given in the morning. He thought that a good deal of the inefficiency of the remedy which had been spoken of was owing to the condition of the stomach arising from the febrile state, in consequence of which it did not absorb properly; so that it would not be digested. The same was true as regards administration by the rectum. If the quinine were given hypodermatically, however, in a short time a good effect would be observed. The temperature would go down to an extent that could not be produced by quinine administered in any other way. The preparation of quinine which he now used for this purpose was the carbamide, on account of its solubility, and he recommended a trial of this method.

It was not worth while to give quinine for its antipyretic effect unless the temperature was over 102°. It should, by no means, be given in every case of pneumonia, as only occasional cases require it. Antipyrin has an excellent effect, if the fever is very high. In protracted cases, in which resolution does not take place, much benefit can be derived from quinine in divided doses in the morning, with Dover's powder at night to secure rest.

Dr. Ripley, in closing the discussion, said that in quite a large number of the cases referred to in the paper the quinine was given by hypodermatic injection; yet the result was practically the same as when given by the mouth. In many of the cases of prolonged pneumonia in children spoken of, he thought there was an associated pleurisy. In young subjects it is often difficult to recognize this. As to the preparation for hypodermatic use, he had employed the muriate in strong solution, and had found it answer very well. He had never produced anything more than cellulitis by the method; and this had not gone on to suppuration. In regard to the matter of antipyretics, he said that sixty cases of measles had occurred at an asylum with which he was connected, and that antipyrin had been resorted to at the onset in a number of them. It was apparent, however, that these cases did not do as well as those which were treated by the ordinary simple methods.

The President remarked that it was not safe to use a concentrated solution in hypodermatic injections, and related a case in which a strong solution of the muriate of quinia was employed. The patient died, and at the autopsy the quinine salt was found deposited in the connective tissue, only the water of the solution having been absorbed.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, January 12, 1887.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. J. H. BRINTON made some remarks

ON THE USE OF WHALEBONE BOUGIES IN THE TREATMENT OF URETHRAL STRICTURES.

He stated his belief that in these instruments we have an efficient mode of treating stricture, provided they be properly constructed, and skilfully manipulated. As he has never been quite satisfied with the whalebone filiforms of the shops, he makes his own, and with these he has experienced comparatively little difficulty in treating stricture, and in relieving obstinate cases of retention. His experience has convinced him that all organic urethral strictures of non-traumatic origin are pervious to the filiform bougie, patiently and systematically essayed. He purchases his whalebone from J. F. Tobin, 82 Duane Street, N. Y., at about two dollars a gross. Each piece will make two bougies. In preparing them he first cuts off the end transversely so as to get rid of any tendency to split. He then rounds the end by rubbing it lightly on a sheet of emery paper gummed upon a board. He then makes the extremity bulb-shaped. He was told that the bulb is usually produced by the action of a file. He makes the bulb extremity by placing the end of the whalebone in a groove on the board and shaves or scrapes it from the end with a very sharp knife. He then shaves down the shank and neck in like manner in the opposite direction, until he has formed a conical neck from three to four inches long, and of almost capillary thickness as it approaches the bulb. The shape of the bulbar ends demands some dexterity in handling the knife, and to insure accuracy he does this under a lens of low power. As the filiform whalebone bougie is the guide upon or over which metallic instruments are to be passed, each one should be carefully fitted. This can be done by frequently passing it upward and downward through the tunnelled perforation in the beak or extremity of each and every instrument, in conjunction with which it may in future be used.

In endeavoring to pass a stricture he makes the first attempt with a single whalebone; if it passes, well and good. If it does not go through, he follows it with others, perhaps five or six, until the follicles or folds of the mucous membrane near the stricture are occupied. Then by patiently essaying the inserted filiforms, he almost always succeeds in getting beyond the stricture at the first sitting. There is a caution to be observed as to the time of making use of filiform instruments. Their application, in cases of tight stricture, should be primary—that is, one cannot expect to succeed with them if they have been preceded on the same day by the attempted introduction of round-ended instruments, the tendency of which undoubtedly is to obscure or close in some way the narrow opening of a resisting stricture, and thus to render its detection more than usually difficult. He always uses the straight filiform. The whalebone, when once introduced, serves as a guide to the metallic catheter, or stretching instrument. This may be the tunnelled catheter, or any of the various forms of dilators or divulsors; preferably, he thinks, that of Sir Henry Thompson, followed by the powerful and most efficient instrument designed by Prof. S. W. Gross, and which registers from 16 to 40 of the French scale.

In using metallic instruments in conjunction with the filiforms, there is one point to which attention has not been directed. We are ordinarily told to slide the metallic instrument over the whalebone through the stricture into the bladder; in so doing, the whalebone may be cut at the seat of stricture. He avoids this accident in this manner: Having passed the whalebone into the bladder, he carries the metallic instrument—threaded on this, as it were—down until he reaches the stricture, the point of resistance. He then ceases to push the metallic instrument along the filiform, but slightly withdrawing the latter to gain a little by the conicity, he grasps both instruments between his thumb and finger, and gently carries them on together. In this way he is almost certain to pass the resisting point, and, if the stricture be single, to reach the bladder.

In employing the stretching instrument he usually separates the blades as far as No. 30 or No. 35 of the French scale, and on its withdrawal, introduces a steel bougie of about the same calibre, to see that all is right, and that the urethra is clear. The bougie is then removed, and is not reintroduced until the third or fourth day. The after-treatment consists in the hypodermatic use of morphia, full doses of quinine, and in a milk diet.

In retention dependent upon tight and irritable stricture, not readily overcome by the catheter, he has often succeeded by simply passing a whalebone into the bladder and leaving it *in situ*. The urine will readily pass along the filiform by capillary action, and the steady dribbling thus established will in a short time empty the bladder. The presence of the whalebone serves also to render the stricture less tight, and so facilitates the after-passage of metallic instruments should their use be considered desirable.

DR. S. W. GROSS said that the younger members of the profession, who are not accustomed to the use of filiform bougies, should not put too much confidence in them, as they do not always pass with readiness through a small stricture, or even through a large one. He differed from the speaker in regard to the usefulness of the twisted bougies. In the great majority of strictures, the orifice is eccentric. A twisted bougie will often pass after straight one has failed, although the urethra has been packed with them. In strictures not the result of traumatism, the obstruction does not arise from the organic stricture itself. A man may have been suffering with stricture for some time, and the calibre of the urethra have been gradually narrowing until the stream of urine becomes very small. In this condition he exposes himself to cold and wet, and in the course of a few hours is unable to pass urine. In such a case the obstruction is not due directly to the organic stricture, but there is superadded spasm of the muscles of the urethra, and it is spasm which we have to overcome rather than the contraction itself. In such a case, the patient being under the influence of an anæsthetic, he carries a medium sized instrument—say one whose shaft measures No. 16 and whose point is No. 13 of the French scale—down to the stricture, supporting, if necessary, the curve of the instrument with the finger

on the perineum or in the rectum. In the majority of cases gentle pressure for a few minutes will enable the instrument to pass into the bladder. He has succeeded in this way in cases where he had failed to introduce a filiform bougie.

The instrument to which Dr. Brinton has referred, he had made more particularly for the purpose for which he uses it. At the time that he invented it, he was a rather firm believer in the treatment of stricture by divulsion. He does not employ this method now, although he would use it in a case of retention of urine. It is no more dangerous than cutting, and cutting is no more dangerous than divulsion, but internal incision can be more accurately limited than divulsion. With the latter method we tear not only the stricture, but also the mucous membrane at some distance in front of and behind it. In a specimen in his possession where divulsion was employed, there were no less than nine rents in the mucous membrane, and the rent in the stricture was oblique and had not gone completely through it. This method will do in superficial strictures, but in hard fibrous strictures we have to supplement this operation with urethrotomy. It is for this reason that he has given up divulsion for internal urethrotomy, and he does not resort to this latter operation so frequently as he formerly did. When the patient is within convenient distance, he much prefers in ordinary cases of inflammatory stricture, and in recent cases more particularly, to resort to gradual dilatation. He has reached the firm conviction that the cases in which a radical cure is produced by divulsion, internal incision, or external incision, are so rare that it is seldom worth while to resort to these operations.

DR. CHARLES B. NANCREDE said that when he intends to do any radical operation, he prefers incision, for then he knows exactly what he is doing. Filiform bougies are not always easily passed through a stricture, even when it is of comparatively large size. Where he has failed to pass the filiform bougie, he has frequently succeeded with a metallic instrument of fair size.

DR. BRINTON said that the remarks which have been made only show that every surgeon operates according to the habit of his own mind and hand. While he does not claim that the method which he has described is better than that of others, he can only say that it is one which he has followed for many years, which has yielded him great success in the past, and to which he looks forward with confidence in the future.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January , 1886.

THE PRESIDENT, C. L. DANA, M.D., IN THE CHAIR.

DR. PUTNAM JACOBI read a

NOTE ON APHASIA WITH REFERENCE TO LOSS OF NOUNS.

Seventeen cases out of a total of 116 analyzed offered this peculiarity, which has not failed to attract the notice of authors. Several explanations have been offered, none of which seemed to the writer completely satisfactory. Anatomical data are not at present sufficient to throw much light on the matter further than to demonstrate that the symptom is probably always associated with diffuse, and not with focal, lesions. These lesions cannot fail to lie on the sensory side of the speech mechanism, and for reasons detailed at length in the paper must especially involve the paths between the auditory and visual centres, through which the auditory impression or sign of the object became habitually associated with the visual impressions. The writer maintained that the act of speech always involves an entire proposition, framed in the suprasensory concept centres (probably the superadded convolutions of Broadbent). This proposition constituted a verbal conglomerate, a unity to the mind expressing it, whatever the number of separate parts into which it might be broken up. Such actual verbal conglomerates remain in many primitive languages, as that of the Greenlanders and North American Indians, where entire sentences are often inflected like a single noun or verb. In our languages the conglomerate or proposition to be expressed is composed of the reminiscences of auditory signs which have become fused with similar reminiscences of visual impressions of things and their relations. If the visuo-auditory paths are interrupted the signs or names of things will be dislocated from their habitual association with the other characters of such things, while the visual impressions themselves remain, and enter directly into the verbal conglomerate. All other parts of speech than nouns, expressing complete intellectual relations, and although remotely connected with impressions registered in the visual centre, are immediately associated only with the processes and registrations of the suprasensory or intellectual centres. While these are intact, therefore, and unless focal lesions have altogether obliterated the memory of language, the speech of relations will be remembered and revived in expression. The objects which are involved in the relations of the conglomerate proposition will no longer be revived in consciousness by their names, but by means of their visual impressions only. These can be expressed by gestures, mimicry, or periphrases, the loss of the auditory sign is thus compensated.

DR. H. D. CHAPIN read a paper on

PERIPHERAL NEURITIS AND THE PAINFUL PARALYSES OF EARLY LIFE.

He said there had been great scarcity of autopsies in comparison to the frequency of paralyses in children. For that reason a very careful clinical study was necessary, interpreted in the later knowledge of anatomy and physiology of the central and peripheral nerves. The writer had met an atrophic form of paralysis differing at its inception, development, and result, from the spinal paralyses with which he was familiar. Most of the autopsies had been made many years after the paralysis, when death had taken place from some other cause. There having been but few autopsies in proportion to the number and variety of cases of paralysis, there seemed rather a slender basis for the theory of exclusive spinal paralysis of childhood. Laborde's case is mentioned where a tabetic neuritis existed with sclerosis of the antero-lateral horns, while the ganglion cells were found normal. Robin's case was cited where no lesion of the cord was discovered. Such a case would show that paralysis is not necessarily always spinal. Barwell's theory was incidentally mentioned. He claimed that infantile paralysis is purely peripheral,

involving the ultimate fibrillæ of the nerves among the muscular elements. Later Leiden advanced a more rational explanation when he considered that in atrophic paralysis there may be neuritis with spinal cord lesion, and that, instead of such forms of paralysis always originating in the spinal cord, they may have their beginning in any part of the motor apparatus, then spreading to other parts or remaining limited to the part first affected. Leiden claims that where complete recovery takes place, the morbid processes always remain peripheric. Leiden's theory is accepted by the author of the paper as affording satisfactory explanation for certain cases that he has observed clinically. The histories of three cases were given in which paralysis was gradual at the onset, and attended by great and persistent pain. Pain was one of the most marked symptoms, and principally at the extremities—legs and feet. Most of these cases lasted several months, and then, to the surprise of the writer, slowly recovered. Atrophy was present. One of the cases appeared strongly rheumatic; in the other two the cause was uncertain. Malarial poisoning appeared to be able to produce a more or less severe form of multiple neuritis resulting in paralysis. The history of a mild case was given which recovered under quinine.

Several cases were related in which children with malarial fever were seized with painful paralysis, lasting in one case over four months, followed by recovery. A possible explanation of pain is that it is due to the marked general congestion of the gray matter of the spinal cord. The author stated that in his cases, and others like them, there were no other symptoms showing irritation in the deeper parts of the cord. The general congestion or myelitis should cause bladder symptoms, bed sores, and other disturbances. Histories of two cases of lead paralysis in young children seen by the author were given. The lesions were regarded as largely peripheric. Cold usually attacks by preference the peripheric system of nerves. The loss of power sometimes following rheumatism is also probably of this nature. Any morbid blood condition appears able to produce a peripheral paralysis in early life, particularly the acute infectious diseases, especially diphtheria. The lesion in diphtheria is now known to be largely peripheric.

The object of the paper is suggestive, not dogmatic. The author has gladly availed himself of recent studies in peripheral neuritis tending to throw light upon some of the paralyses of children which have caused much perplexity. The great differences in the clinical behavior of paralyses in early life, in duration and curability, must admit of different anatomical and pathological explanations.

Dr. M. ALLAN STARR did not know of any recorded case in a patient under twenty-four years of age in which a lesion of a peripheral nerve had been found at autopsy which would account for the paralysis; and while there was great probability in the statements made by the author, they yet lacked confirmation by autopsy. The points had been brought out very well with regard to the distinctions between peripheral neuritis and anterior poliomyelitis, but he would take exception to what had been said regarding the rapidity of the onset. There were many cases of acute onset of peripheral neuritis, the patient having fever and chill, and the limbs within twenty-four hours becoming entirely immovable. Too much attention could not be given to the usually great tenderness in the muscles and nerves in multiple neuritis.

Dr. RUDISCH said that he was the first to observe, as long ago as eight or nine years, a form of polioneuritis leading to paralysis and atrophy, and which followed affections of the joint, often so-called rheumatic affections. We now saw often enough an affection of one or more joints with inflammation, followed after awhile by paralysis, usually curable.

Dr. FISHER said a girl, thirteen or fourteen years of age, was brought to the dispensary with the history that one morning, after taking cold, she woke up with paralysis of the upper and lower extremities. At that time she had only paralysis in one leg, which he supposed, without thought of neuritis, to be ordinary poliomyelitis. Rapid improvement took place, and she recovered within six weeks, and the minister who brought her reported the case as one cured by faith. Dr. Fisher was unable to say whether the case was an affection of the anterior cornua or one of multiple neuritis.

Dr. SACHS thought we should not be influenced too much by the present fashion, and call all, or most, of the cases formerly regarded as poliomyelitis cases of multiple neuritis. Referring to one of the cases related in the paper, and the symptom of pain, he said too much stress should not be laid upon it unless it was severe, persistent, and located distinctly along the tract of a peripheral nerve.

Dr. LESZYNSKY regarded pain as a prominent symptom of neuritis, absent in the majority or all of the cases of simple poliomyelitis. The pains present in some of Dr. Chapin's cases reminded him of the pain from straining the tendons of the extensor muscles which had been for some time in a paralyzed state.

Dr. CHAPIN thought that a neuritis would occasionally explain cases which could not be accounted for on the supposition of a spinal lesion, and he would rather say halt! to the universal spinal cause of disease. With regard to pain, it is difficult to locate it along a particular nerve in children, but in his cases it was acute and persistent, and not due simply to stretching of tendons.

CORRESPONDENCE.

THE MEDICAL SIGNERS OF THE DECLARATION OF INDEPENDENCE.

To the Editor of THE MEDICAL NEWS,

SIR: *The Boston Medical and Surgical Journal* makes the following remarks on a portion of my Centennial Address:

"The statement in the recent address of the President of the College of Physicians of Philadelphia, that Rush 'was the only physician whose name is on that energetic arraignment of the Crown' (the Declaration of Independence) should not pass unchallenged. Josiah Bartlett, of New Hampshire, and Lyman Hall, of Georgia, were successful practising physicians; Oliver Wolcott, of Connecticut, studied for the profession."

My critic might have added Matthew Thornton's name to his list. My answer to the friendly challenge is this:

Josiah Bartlett is said by Sanderson and Thacher to

have studied medicine with Dr. Ordway, of Amesbury, Mass., and completed his education in 1750. Certainly, then, at no school of medicine. He became a statesman and judge, but ceased to practise medicine.

Lyman Hall, born in Connecticut about 1731, is said by Sanderson to have attained a proper knowledge of medicine at an early period of life. He moved to Georgia in 1752. It seems certain that he owed his title of doctor solely to the fact that he studied with a practitioner of physic. He, too, was not a graduate, and he, too, gave up his career in medicine for politics, and was finally Governor of Georgia.

Oliver Wolcott began to study medicine, but never pursued it and never practised it. We may leave him out of the question.

Matthew Thornton was born in Ireland about 1714. He studied with Dr. Grant, of Leicester, Mass., and practised in Londonderry, New Hampshire. Of Thornton, Thacher conjoins this statement, quoting N. H. Hist. Coll.[1] Thornton seems never to have obtained a diploma, and he, too, may therefore be classed as only a practitioner of medicine; nor can I discover that he pursued a medical career after going to Congress.

None of these men were graduates in medicine, none of them would now be classed by us as physicians, in the higher sense in which we apply the term. Rush, on the contrary, was a graduate of Edinburgh, and never gave up the pursuit of medicine. He alone, of those named, was a titular M.D.

Yours truly, S. WEIR MITCHELL.

[illegible]

INFLUENCE OF THE CHARLESTON EARTHQUAKES ON HEALTH.

To the Editor of THE MEDICAL NEWS,

SIR: In my recent paper on the effects upon health produced by the earthquake shocks in Charleston, my principal object was to collect, record, and preserve a succinct account of all the phenomena observed.

Among the most striking of these—noticed by numberless persons—were sundry sensations closely resembling those ordinarily produced by the shocks of electro-magnetic batteries, viz., pricking sensations, "needles and pins," feelings beginning in the fingers and toes and extending up the arms and legs. Many of these occurred in adult *males*, and in children of both sexes, too young for any "hysteroidal" element to prevail. I do not think that all these sensations should be ascribed to fear, or to purely nervous disturbances; for similar results have not always been observed in the numerous instances where large numbers of people have been exposed to sudden danger, as in war, accidents, burning or falling buildings, etc.

There had been marked absence of electrical disturbance, rains, or storms, for months preceding the earthquake.

My respected colleague, Professor Guitéras, in his friendly comments on that part of my paper, differs as to the explanation, and he makes apparently a strong point in claiming that there was no sensible disturbance of the electrical batteries in this city.

This may be true, as I am likewise informed; but even without the intervention of an earthquake the atmosphere is sometimes highly charged with electricity, but not in sufficient amount to produce the effects recently observed. My object was to give in a philosophical spirit the natural history of the catastrophe, and cite all its results, whether or not the true explanation was afforded, upon which men will differ.

One of the young ladies engaged in the telephone office in this city, who was in Savannah during the great shock, informs me that she experienced decided electrical disturbances in every way resembling those from an electrical battery.

A word with regard to an article by Surgeon Carter, of the U. S. Army, recently published in your columns.

I was much gratified by the record of his observations respecting the use of a prescription advised by me for the prevention and treatment of diphtheria, though disappointed to find that in the adobes of the Gila River, which were crowded with Mexicans, who lived under very poor hygienic conditions, the prescription failed to prevent the disease.

Dr. Carter states that he derived special benefit also from the bichloride of mercury. I, also, in my original communication to THE NEWS, advised the combined use of the bichloride where the poison was concentrated, and the danger of infection very great.

F. PEYRE PORCHER, M.D.

ANTISEPTIC HYPODERMATIC INJECTIONS IN BACTERIAN MALADIES.—Many diseases are caused by microbes, and as every microbe has its known microbicide, it becomes necessary to know how to employ the latter in subcutaneous injections. M. MEUNIER believes that he has discovered a medium through which all the microbicides that are not dangerous to the economy may be injected hypodermatically without causing either swelling, abscesses, or pain. This medium is pure vaseline (density, 0.820), which dissolves thymol, menthol, the essences of eucalyptus, cubebs, santal, copaiba, mint, and of cinnamon—in a word, all the hydrocarbons whose formula is $C^{n}H^{2n-4}$, and $C^{20}H^{n}$; and also carbolic acid, camphor, chloride of camphor, creasote, sulphide of carbon, iodoform in solution in the essences, and even alkaloids, such as cocaine, digitaline, etc. Many microbicides, antiseptics, and medicines may, therefore, be employed subcutaneously which are not easily digested and absorbed by the gastro-intestinal tube, and in this way accurate dosing of the active principle may be obtained. The following are the general formulæ which M. Meunier proposes to employ in subcutaneous injections:

Essence of eucalyptus . . .	5 parts.
Vaseline, chemically pure (D. 0.820)	20 "

Each Pravaz syringe contains twenty centigrammes of eucalyptol. The mixture should be well shaken, allowed to repose, and filtered through three papers. The solution will then be found to be clear and limpid. Prepare in the same way the solution of the essences

[illegible] (By Robert Wain

whose formula is $C^{2n}H^{2n-4}$—that is to say, the essences of cubebs, thyme, santal, copaiba, mint, etc. These essences may be associated, taking care that the proportion of the essence to the vaseline is 1 to 5, in order to avoid pain and swelling.

Eucalyptol	5 parts.
Iodoform	0.25 part.
Vaseline	20 parts.

Dissolve the finely powdered iodoform in the essence; add the vaseline, agitate, and filter through three papers. Each Pravaz syringeful contains twenty centigrammes of eucalyptol and one centigramme of iodoform.

Sulphide of carbon	1 part.
Vaseline	15 parts.

Mix and filter as above.

Clinical observations will indicate the number and the quantity of the injections to be employed in different maladies. M. Meunier concludes that, with vaseline as a vehicle, injections of the non-toxic microbicides may be made in the subcutaneous connective tissue, and probably in all the other tissues, without inflammation, reaction, or pain, and thus arrest the evolution of microbes; and that the dose may easily be determined for each tissue according to toleration. In the numerous experiments with these injections, M. Meunier met with only one simple inflammatory reaction without suppuration, even with extreme doses.

STATE BOARD OF HEALTH AND CHARITIES OF NEW YORK.—Governor Hill, in his annual message to the Legislature, has again recommended the abolition of the State Board of Health and the State Board of Charities, and the concentration of the honors of these bodies under single heads.

OFFICERS OF THE NEW YORK COUNTY MEDICAL ASSOCIATION.—The annual meeeting of the New York County Medical Association was held at the Carnegie Laboratory, January 17th, when the following officers were elected:

President.—Dr. John Shrady.
Vice-President.—Dr. J. R. McGregor.
Recording Secretary.—Dr. P. Brynberg Porter.
Corresponding and Statistical Secretary.—Dr. Glover C. Arnold.
Treasurer.—Dr. Charles Ellery Denison.

OBSTETRICAL SOCIETY OF BOSTON.—At the twenty-sixth annual meeting of the Obstetrical Society of Boston, held January 8, 1887, the following officers were elected for the ensuing year: *President*, Dr. William L. Richardson; *Vice-Presidents*, Dr. O. W. Doe, Dr. John Homans; *Treasurer*, Dr. E. J. Forster; *Recording Secretary*, Dr. C. M. Green; *Corresponding Secretary*, Dr. J. Stedman; *Prudential Committee*, Dr. William Ingalls, Dr. J. G. Blake, Dr. F. W. Draper, Dr. J. W. Elliott, Dr. C. M. Green, *ex officio; Publishing Committee*, Dr. Alfred Hosmer, Dr. J. R. Chadwick, Dr. C. E. Stedman. Dr. W. W. Wellington, of Cambridge, was elected an honorary member.

DEATH OF THE "LIVING SKELETON.—The "Living Skeleton," pleasantly and familiarly known to some of the attendants at Dr. Holmes's anatomical lectures, has at last become a dead skeleton. Mr. Sprague, the individual in question, has just died, at the age of forty-six, and the weight of forty pounds. He has bequeathed his remains to the Harvard Medical School, and it is to be hoped we shall soon know what was the missing link in his assimilative system. The deceased was personally inclined, as we remember, after considerable association with admiring medical men throughout the country, to attribute his difficulty to atrophy of the thoracic duct.—*Boston Medical and Surgical Journal*, January 13, 1887.

WOMEN AS SANITARY INSPECTORS.—A petition with one hundred signatures has been presented to the New York Health Board asking the appointment of six women on the corps of sanitary inspectors.

A MORE HUMANE MODE OF EXECUTING THE DEATH PENALTY.—There has been considerable discussion on this point, of more or less merit of late, in both the lay and scientific journals. There can be no doubt that the present mode of hanging is alike barbarous and discreditable to modern ingenuity. With the present extraordinary progress in electro-mechanics, there is evidently no reason why electricity should not be employed for the purpose. The dynamo-machine would appear to meet every theoretic and practical indication. When thus employed, death would be instantaneous, and entirely devoid of those revolting features which have so long disgraced the present methods.—*New York Med. Monthly*, January, 1887.

CREMATION IN NEW YORK.—Although the New York Cremation Society owns a fine crematory, it has been used but infrequently, the bodies of only two members of the Society having been incinerated during the past year.

THE COLLEGE OF PHYSICIANS AND SURGEONS OF NEW YORK.—The building and lot on the corner of Twenty-third Street and Fourth Avenue belonging to the College are said to have been sold for the sum of $160,000. Possession is to be given the purchaser in September next, if the new college building on Tenth Avenue is completed by that time.

ASYLUM FOR INEBRIATES AT MILAN. — The first Asylum for Inebriates has just been opened near Milan, Italy. It is intended for the better class, who can pay for the best medical care and surroundings. In all the hospitals for insane, wards are set apart for inebriates, and their treatment, as partially insane, has been carried on successfully for many years, but this is the first organized effort to treat them in a separate hospital.

THE LACAZE PRIZE.—The great Lacaze prize of 10,000 francs, which is awarded every four years for the best work on the treatment of fevers, typhoid in particular, has just been given to Dr. Albert Robin for his work called "Leçons de Clinique et de Thérapeutique Médicales." M. Robin is one of the professeurs agrégés at the Faculty, and a relative of the late Professor Robin.

THE RUSSIANS are not in all respects a nation to be imitated, but there are some things we might learn even

from them. For instance, a Russian doctor who fails to attend a patient when called upon to do so, commits a legal offense, the punishment for which is a fine varying from 5 to 100 rubles, or, in case of gravity, a term of three months' imprisonment. This is a much better means of keeping a medical man up to the mark, where the patient is not a "paying" one, than the remote prospect of an inquest before a medical coroner. I observe, too, that in Russia medical fees are regulated by law, which is also not a bad idea.—*London Truth.*

Poisoned by a Cobra.—The [illegible], Naturalist [illegible], in Ceylon, reports the death of the taxidermist of the Victoria Museum in that town from the bite of a cobra, under curious circumstances. While feeding a cobra, which he thought was harmless from previous extraction of the poison bag, it suddenly bit his hand. For a few minutes he took no notice, thinking the bite harmless, but pain and nausea soon began. Carbolic acid was applied, ligatures were bound round the arm, an incision was made at the bite, and the blood of the arm was wholly removed. Various antidotes were used, but the unfortunate man lost the power of speech, and soon after every muscle seemed to have become paralyzed, and breathing entirely ceased. Artificial respiration was, therefore, resorted to, and this operation was unceasingly continued for nine hours, when at last the patient made an attempt to breathe, and soon regained consciousness enough to make his wants known. He steadily improved until the Friday, the accident having taken place on a Wednesday, and then astonished those around him by stating that during the severe operation of Wednesday night he was conscious of all that was taking place, but was unable to make his feelings known, not having power over a single muscle. It would seem that the poison paralyzed the nerves of motion, but not those of feeling, for he could see and hear and feel, although the physician, even by touching the eyeball, could get no response either of feeling or consciousness. His partial recovery was, however, followed by a high fever and inflammation of the lungs, and he died, perfectly conscious, on following Sunday.

Preventive Inoculations in Hydrophobia in Vienna.—Dr. Ullmann, assistant of Professor Albert, who has spent some weeks in Paris, studying Pasteur's method of preventive inoculations for hydrophobia, has recently established in Vienna a station for preventive inoculations. From June 28th till now eighty-five persons bitten by rabid animals were inoculated with the best success. The rabid condition of the animals by which the patients had been attacked was stated in all these cases. According to the reports received, all the patients are in good health.

Unmuzzled Dogs in London.—The metropolitan police order for the muzzling of dogs, which came into force December 10, 1885, was last week withdrawn. That it has been extremely beneficial in its operation is shown by the fact that whereas in the first week of its enforcement there were recorded 46 cases of rabies, and 1 death; in January the number of cases fell to 27, and 1 death; in February there were 14 cases, and no deaths. The number of rabid dogs found in the streets since this order has been in force has also sensibly diminished. In July the number was 16, in August 13, September 9, October 4, and in November about 12. During 1885, there were no fewer than 373 cases of rabies reported to the metropolitan police, and 26 deaths occurred in London alone.

The Late John P. Gray, M.D.—The members of the Council of the New York State Medical Association, while humbly submitting to the decrees of Providence, realize with much grief that the year now closing is made notably sad in the loss by death of so many of their Fellows whose labors have largely contributed to the honor, dignity, and usefulness of the medical profession.

They now mourn the loss of the second president, Dr. John Purdue Gray, whose aid, wise councils, and personal work, have been of such signal service.

In common with all the Fellows of the Association, and with the medical profession at large, they sorrow for the death of one who had rendered himself so useful to the State in the guidance of the charitable work in the department of medicine, in which he had become a shining light.

The Council, therefore, resolved that the above be published in the forthcoming volume of the *Transactions* of the Association, and in the medical journals, and that a copy thereof be transmitted to the family of the deceased. E. D. Ferguson,

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. L. SATURDAY, FEBRUARY 5, 1887. No. 6.

ORIGINAL LECTURES.

THE MIDDLETON GOLDSMITH LECTURES.

Delivered under the Direction of the New York Pathological Society.

BY M. ALLEN STARR, M.D., PH.D.,

PROFESSOR OF NERVOUS DISEASES IN NEW YORK POLYCLINIC.

LECTURE I.

MULTIPLE NEURITIS AND ITS RELATION TO CERTAIN PERIPHERAL NEUROSES.

IN inaugurating the course of lectures which bears the name of the founder, it is becoming that some expression of gratitude should be made to Dr. Middleton Goldsmith. This can hardly be associated with any form of personal encomium, since that would be as distasteful to him as it is needless before this Society, which owes its existence in part to his exertion. It is proper, however, to emphasize our appreciation of the motives which have led to the establishment of this lectureship. Every one knows that in the rapid progress of medical science, in the great and needful division of labor which that progress has made imperative, there is offered to each individual worker a vast mass of facts which cannot be easily grasped or even readily comprehended. To classify these facts, to weigh their importance, to draw logical conclusions from them, and to present these conclusions in a clear and accessible form is a work of no little magnitude, but of absolute necessity. To accomplish this specialists are at work in every department, and it may be well to emphasize the fact that it is the necessity for their labor, rather than any temporary fashion, that has led to that specialization in medical science which is so often harshly criticised. But special studies lose half their value if they are not made generally available. And it is just here that a lectureship such as this has its use. It enables the results of individual labor to reach beyond the specialist, to be placed before the general practitioner in a simple but comprehensive way. There is, therefore, no means by which an individual can make his influence more widely and permanently felt than by the endowment of such a foundation. For when his personal activity has of necessity ceased with the natural termination of an honorable career he may be sure that, yearly, facts and results are proclaimed in his name of immeasurable service to his successors and of benefit to the profession.

And now, before proceeding to the subject which is to occupy our attention for a time, let me express my obligation for the honor which this Society has conferred in inviting me to inaugurate this course of lectures. It is an honor to which I have no claim, and the duty incurred is one which I feel incapable of performing satisfactorily. I must beg your indulgence in the performance of the task you have laid upon me, and if I succeed in eliciting your interest I know that it will be because the subject we are to study together has a novelty which may compensate for the defects of its presentation.

The discovery of a new disease is never made suddenly. It is a gradual process, and certain stages in the progress toward its complete recognition may be observed. There is first the period of clinical observation, when isolated cases of an unfamiliar and mysterious affection are recorded as curiosities. To this succeeds the period of diagnosis, when, by a comparison of the now numerous cases, a clinical picture of the disease is gradually filled out. In this stage there is much to impede the progress of discovery; for, not content with an analysis of symptoms, and a grouping of cases, the majority of observers offer theoretical explanations of the nature of the new affection, and an element of speculation enters which often obscures the facts. There is, however, a real progress in this period, for it is characterized by inductive reasoning from fixed data, and as a result reliable conclusions are reached which make a diagnosis possible. The third period is that of pathological discovery, where the morbid changes lying at the base of the disease are accurately ascertained. In this stage erroneous theories are eliminated, true explanations for various symptoms become self-evident, and the exact nature of the affection is determined. The disease has now a status of its own. And at first this might seem to be the final stage in the progress of discovery. But it is not. There remains a period of etiological classification, when conditions, formerly supposed to be dissimilar, are found to have a common basis, when the pathological changes are ascertained to be the same, although the clinical pictures have varied, and when classification of the various forms is rendered possible and a definition of the disease is reached.

Such a gradual advance toward general recognition is well illustrated by the history of multiple neuritis, which is to engage our attention at the present time.

I think we may claim that one of the first cases presented was by an American physician, Dr. James Jackson, of Boston, in 1822.[1] In a paper "On a Peculiar Disease Resulting from the Use of Ardent Spirits," which he named arthrodynia, he gives a most graphic picture of what we now know to be one form of multiple neuritis. He says, "This disease comes on gradually. It commences with pain in the lower limbs, but especially in the feet, and afterward extends to the hands and arms. The hands may be affected first in some instances, and in all cases in an advanced state the pain is more severe in the feet and hands than in the upper part of the limbs. The pain is excruciating, but varies in degrees at different times. It is accompanied by a distressing feeling of numbness. After the disease has continued a short time, there take place some contractions of the fingers and toes, and inability to use these

[1] New England Journal of Medicine and Surgery, vol. xi, p. 371.

parts freely. At length the hands and feet become nearly useless, the flexor muscles manifesting, as in other diseases, greater power than the extensors. The whole body diminishes in size, unless it be the abdomen, but the face does not exhibit the appearance of emaciation common to many visceral diseases. The diminution is especially observable in the feet and hands; and at some time the skin of these parts acquires a peculiar appearance. The same appearance is noticed in a slighter degree in the skin of other parts. This appearance consists in a great smoothness and shining, with a sort of fineness of the skin. The integuments look as if tight and stretched, without rugæ or wrinkles, somewhat as when the subjacent parts are swollen; but the skin is not discolored. Yet in this disease there is not any effusion under the skin, and the character which this assumes arises from some change in the organ itself. The most characteristic symptoms are manifested in the limbs, but the pain is not limited to these —and other symptoms are exhibited in other parts. The pain sometimes shoots suddenly up one or both legs, and in one case it frequently passed up the back and then forward to the pit of the stomach. The functions of the stomach are always impaired; the mind is weakened; sleep is prevented by pain. I believe that this disease is always fatal when the use of spirituous liquors is not abandoned before the powers of the digestive organs are greatly impaired."

It is hardly possible, even at the present day, to add to this description, which portrays in strikingly vivid language the main features of one form of multiple neuritis.

The next observations of importance in establishing a clinical picture were made by Magnus Huss, who, in his work upon chronic alcoholism, in 1852, gave a very complete description of alcoholic nervous symptoms, dividing the cases into paralytic, anæsthetic, convulsive, epileptic, and hyperæsthetic forms. But not content with the clinical side, he advanced to pathological hypothesis, and ascribed all the various symptoms to lesions in the central nervous system. His description was amplified and completed by Lancereaux, in 1864, in an article upon alcoholism in the *Dictionnaire Encyclopédique des Sciences Médicales*. But the pathology of the disease was still a matter of speculation.

In 1855 the great work of Duchenne was published,[1] and in it a number of cases are recorded which we now recognize as multiple neuritis. In these cases there were sensory disturbances, consisting of pain, numbness, and loss of sensation; motor disturbances, consisting of paralysis, with atrophy, especially marked in the distal parts of the extremities, and attended by a loss of faradic contractility in the paralyzed muscles; and cyanosis, coolness, and increased sweating in the affected limbs. Duchenne grouped these cases together under the title "Paralysie Générale Spinale Subaigüe Ascendante," because he thought a gradual advancing lesion in the spinal cord, from below upward, would explain the symptom. It is true that he found no macroscopic change in the cord in the only case in which he made an autopsy. But when, under the leadership of the French school, from 1860 to 1865, the microscopic appearances in nervous lesions began to be studied, the hypothesis of Duchenne at once appeared to be verified, for it was found that such symptoms as numbness, pain, and anæsthesia were associated with lesions of the posterior columns of the spinal cord. And it was also proven that atrophic paralysis was caused by a degeneration of the ganglion-cells of the anterior gray horns of the cord, not necessarily visible to the naked eye. It seemed an easy step to the conclusion that when these symptoms occurred together, the entire spinal cord was the seat of disease, and that wherever they occurred a spinal lesion was progressing. The pathology of this form of paralysis appeared to be definitely ascertained, and for many years the fallacy of such a conclusion was not detected. All atrophic paralysis was invariably referred to spinal lesions, because spinal lesions may cause atrophic paralysis.

But facts rarely accommodate themselves permanently to theories, and after a time a mass of very unwieldy facts began to accumulate. Cases of atrophic paralysis without spinal lesion were observed, and these threw doubt upon the theoretical pathology. The period of true pathological observation had begun, and gradually went on to completion. In 1864 Duménil reported the following case, which deserves to be cited, as it is the first in which an autopsy established the existence of a widespread disease in the peripheral nerves as a cause of sensory, motor, and trophic symptoms.

Observation I.—A tailor, aged sixty-one, after suffering from prickling in the toes for two weeks, was suddenly taken with weakness in the left arm and right leg, and a few days later by the same paresis in the left leg. Within five days he could not stand or walk. The paralyzed feet hung flaccid, and were totally paralyzed; the thighs could be moved freely. Anæsthesia was found on the right sole and calf, and on the left foot and outer side of the leg. In the muscles of the hands and forearms a considerable atrophy, with paralysis, developed. The faradic contractility was abolished in the paralyzed muscles. He complained of a painful numbness in the paralyzed limbs up to the knees, and involving the hands. No improvement; death in four and a half months.

Autopsy: Spinal cord and nerve-roots were normal. The finer nerve branches in the legs and hands were degenerated, only a small number of nerve-fibres being found. Single fibres showed no continuous myelin sheath, but this was segmented and granular. There was an increase of connective tissue, and many fat-cells in the nerves.[1]

This case being of an anomalous character excited very little attention. Two years later, however, Duménil reported another, and published an elaborate article on peripheral paralysis, in which he said: "My own observations have convinced me firmly that many paralyses of obscure origin are caused by true spontaneous neuritis."[2] The second case, which, with the first, led to this conclusion, has been cited by Leyden as a case of neuritis, but it does not conform to any of the types of multiple neuritis, and is open to some doubt from the results of the autopsy, since numerous foci of

[1] Duchenne. Gaz. Heb., 1864, p. 203, and Gaz. Heb., 1866, [illegible].

[2] Ce que j'ai observé me donne la conviction intime que bien [illegible] véritables névrites spontanées. Gaz. Heb., 1866, No. 4.

disease were found in the spinal cord. We, therefore, pass it by.

Singular as it may seem, an interval of ten years elapsed before another case of similar nature, accompanied by a record of *post-mortem* examination, appeared. Then Eichhorst, of Berlin, reported the following interesting history:

Observation II.—A female, aged sixty-six, after suffering daily for two weeks from a chill, fever, and sweat, attended by malaise, anorexia, and constipation, noticed an œdematous swelling of both feet and legs, and complained of pain in the abdomen. A week later, on admission to the hospital, these symptoms continued. The urinary examination was negative. Three days after admission she suddenly felt a severe boring pain in the left leg, shooting into the toes, and at the same time a profuse sweat broke out over the calf and back of the foot. A few hours later a total paralysis was found in the muscles supplied by the peroneal nerve, with a marked anæsthesia. The electric reaction, at first preserved, was found two days later to be gone. After six days, during which she had no further chills, a paralysis of the anterior tibial nerve developed, and soon after of the posterior tibial nerve also. One week later entire paraplegia of the legs, with anæsthesia, severe pains, continual sweating, increasing œdema, and loss of the tendon reflexes had ensued. There followed a paralysis of the left, and soon after of the right, radial nerve. Moderate fever continued, and albuminuria appeared. Three weeks after her admission sudden blindness developed, the ophthalmoscopic appearances being at the time normal; the patient then lay in bed with eyes closed, unable to move a limb. The extremities perspired constantly, and were tender, any pressure on nerve-trunks being very painful. In the face there was no trouble, and the senses were normal except that of sight. No trouble in swallowing. Nothing abnormal about the viscera during the entire disease. No irregularity of pulse or respiration. Death occurred on the forty-fourth day of the disease.

Autopsy: Spinal cord absolutely normal. The nerve-trunks in the bicipital grooves appeared intensely red to the eye, the perineurium being discolored and the endoneurium blood-red. The same appearance was noticed in the large nerve-trunks of the arm in their course, as well as in the left tibial nerve. The microscopic examination showed a remarkable distention and tortuosity of the bloodvessels of the perineurium; the vessel-walls were thickened, their nuclei increased. In the vicinity of the vessels a large number of lymphoid cells were found, which everywhere followed the vessels and infiltrated the connective tissue. There were also numerous fatty cells. The connective-tissue fibrillæ of the perineurium were thickened, shining, and swollen; their nuclei were increased and partly infiltrated with fat granules. Similar changes were seen in the endoneurium, viz., numerous extravasations of blood, which separated the nerve-fibres and compressed them. The nerve-fibres showed marked degeneration, especially those lying next the endoneurium, consisting of disintegration of the myelin sheath, and a distention and spindle-shaped swelling of the individual nerve-fibres. The nuclei of the sheath of Schwann were not increased in number, but the protoplasm about them was coarsely granular and opaque. The cells of the endoneurium were everywhere wanting, being replaced by fatty granular cells, even between the uninjured fibres.[1]

This is the first case to be found in which the microscopic appearances are described with sufficient detail to be satisfactory. It is to be noticed that here the lesion was an acute inflammation, and was, apparently, a diffuse one, both interstitial tissue and nerve-fibrils being involved in the process. That it was primarily an interstitial inflammation, and that the affection of the nerve-fibrils was secondary, due to pressure of the products of exudation, is clearly seen in the fact that those fibres were more seriously affected which lay near vessels, while the deeper fibres in large bundles were not at all degenerated. The appearance of the fibres was such as occurs in any degeneration from pressure. There is no reason, therefore, to believe that the process began diffusely.

As to the symptoms in this case, it is to be remarked that they were ushered in by an acute febrile movement with chills, and that severe pain was an early and prominent symptom; also, that œdema and sweating were present; and that the optic nerves were involved.

The clinical picture in the following case of Joffroy, published three years later, was somewhat different, as was also the pathological condition.

Observation III.—A washerwomen, aged thirty-three, in the last stage of phthisis, was admitted to the hospital on March 5th. In February she had noticed a rapidly increasing weakness in her legs, and at the time of admission she could not walk or raise her feet from the bed. She could flex the knees but not extend them. There was no contracture, and the muscles were relaxed and flabby. Sensations to pain, temperature, and pressure impressions, were normal, but the muscular sense was lost, and reflexes were diminished. She showed such a degree of mental weakness that tactile sense could not be tested. She had no shooting pains, no loss of control over bladder and rectum, no bedsores. Two weeks later the arms became involved in the paralysis, and atrophy, incoördination, and loss of muscular sense, with fibrillary motions, developed within a few days. There was great diminution of faradic excitability in all the paralyzed muscles. At the end of ten days the arms were entirely powerless, but retained their sensibility. On April 7th she died.

Autopsy: A chronic meningitis of the brain explained the mental symptoms. The spinal cord was normal. The nerves appeared normal; but microscopic examination showed very marked degeneration in all the nerve-trunks, but especially in the sciatic, radial, and ulnar nerves. There was a segmentation of the myelin sheath, which at places was reduced to a finely granular mass. Many sheaths of Schwann were filled with this mass, others were empty. The nuclei of the sheaths of Schwann were increased in number; all the spinal nerve-roots were normal. The changes in the nerves were followed down into the fine terminal branches in the thenar muscles. The muscles were atrophied and showed fatty degeneration.[2]

Here, in contrast with the preceding case, it is to be noted that the lesion was not attended by congestion of the nerves, or by any exudation of lymphoid cells, or by

[1] Eichhorst: Virchow's Archiv, Bd. 69, S. 265, 1876.

[illegible]

marked interstitial changes. The affection was a true parenchymatous inflammation, with degeneration of the myelin sheath and axis-cylinder. As a result, the macroscopic appearance of the nerves was not such as to attract attention, and it required a microscopic examination to demonstrate the changes present. Joffroy, who reports this case as one of general spontaneous neuritis, finds the lesion identical with that observed in cases of localized neuritis occurring from cold, from lead palsy, or as a sequel of the infectious diseases. In regard to the symptoms, also, the case contrasts strongly with the preceding one. The patient had phthisis. The disease advanced more slowly. Pain was absent, and the sensory symptoms were by no means prominent, the muscular sense being the only one affected.

In 1880, the following cases were observed by Leyden in the Charité Hospital of Berlin, in both of which changes were found in the peripheral nerves. They are cited because they not only enlarge our clinical picture, but confirm the pathological conditions already described.

Observation IV.—A sailor, aged twenty-five, was suddenly seized with severe tearing pains in all four extremities, especially near elbows and knees, which were swollen, white, indurated, and very tender. The pains shot down the limbs, and were attended by formication, and by diminished sensation in fingers and toes. High fever accompanied the onset. In a few days, as the fever subsided, a paretic condition with muscular atrophy was noticed in the forearms, and to a less extent in legs and feet. A gradual improvement took place in the course of a few months in the lower extremities, but the paralysis and atrophy in the arms increased in degree, and the appearance of the hands resembled that seen in lead palsy. There was a reaction of degeneration in the muscles paralyzed. A year after the onset he died of chronic nephritis.

Autopsy: A sclerotic atrophy of both radial nerves was found. The nerve-sheath was thickened. The muscles were considerably atrophied. The anterior spinal nerve-roots, as well as the cells in the anterior horns, and the entire spinal cord, were normal. In the nerves of the lower extremities no changes were visible.[1]

Observation V.—The second case was that of a merchant, aged thirty-one, who noticed about Christmas, 1878, a feeling of formication in the toes and sole, of first the left, and then the right foot. This continued more or less severe, without any motor disturbance, until July 10th, when he found his legs heavy, and in two days this had so increased that he could not walk. At the same time a constant formication in the soles of the feet was felt. Within a few days similar symptoms appeared in the arms and hands. On admission to the hospital on July 17th, he complained of weakness of the legs and loss of sensation in the hands, also burning pain in the left hand and inner side of the left knee. The motion of the legs was powerless and uncertain, and there was paresis of the extensors of the hands and fingers. Sensation was much impaired in the periphery of the extremities; the tendon reflexes were abolished, the muscles flabby. The electrical examination showed a loss of faradic contractility, and a great diminution of galvanic contractility in the affected muscles. The liver was tender, and there was a slight jaundice; pulse 70; no fever. The paralysis increased slowly in extent and severity, and was accompanied by paræsthesia, pains, and diminished sensibility. The muscles atrophied, and showed the reaction of degeneration. After six weeks slight fever began, with rapid pulse and dyspnœa. The pains affected the upper part of the thorax, and the spinal column became sensitive as low as the eighth dorsal vertebra. During the last days small rapid pulse, severe dyspnœa, purely costal respiration, delirium, somnolence, and exhaustion were noticed, and on September 3d he died.

Autopsy: The spinal cord was normal, the gray and white substance intact, the large ganglion-cells in normal form and number, though a few seemed to present a slightly swollen, glassy appearance which Leyden considered the first indications of trophic disturbance. The nerve-trunks, especially the radials and peronei, presented the appearance of a high degree of fatty degeneration and atrophy. The myelin sheath was either wholly wanting or greatly divided and split up, and in a state of fatty degeneration; the axis-cylinder seemed varicose from deposits of fat in it. A marked infiltration of lymphoid cells, especially between the endoneurium and nerve-fibres, was noticed, more marked along the course of the small arterioles. These changes were present in a greater degree in the peripheral branches of the nerves, and seemed less in the nerves near the cord.[1]

It will be noticed that here the lesion corresponded quite closely to that in the case of Eichhorst.

Impressed by the striking features of these two cases, and by their similarity, both in clinical symptoms and pathological changes, to the cases of Duménil, Joffroy, and Eichhorst already cited, Leyden undertook a review of atrophic paralysis.[2] He showed the confusion which had come from blindly referring all such cases to a single lesion in the spinal cord. He proved that previous authors had erroneously grouped together several diseases distinct from one another, both in their course and in their pathology. One of these is poliomyelitis anterior, acute and chronic, occurring in children and adults; a disease of the anterior gray horns, with local foci of inflammatory degeneration; a disease characterized by motor and trophic symptoms of peculiar distribution and typical course. A second of these is progressive muscular atrophy, with its corresponding bulbar affection, glosso-labio-laryngeal paralysis; a disease of the anterior gray horns and of the motor cranial nerve-nuclei, of a chronic degenerative, non-inflammatory kind; a disease characterized by trophic and motor symptoms of different distribution, nature, and progress from the first disease considered. A third disease is pseudo hypertrophic paralysis, in which a fatty deposit in the muscle conceals the real atrophy in progress; a disease of childhood, but not due to any spinal affection; a disease of the muscular tissue itself. And lastly, he drew the picture of multiple neuritis, a disease due to degenerative processes in the nerves, independent of spinal lesion; a disease characterized by atrophic paral-

[1] [illegible]

[2] Leyden: Zeitschrift für klin. Med., I. Ueber Poliomyelitis [illegible]

ysis, associated with marked sensory symptoms, and with tenderness of the nerve, by a typical course, and, usually, by a favorable termination. By this article Leyden established the status of multiple neuritis as a distinct disease. Its symptoms were analyzed. Its lesion was described. The pathological stage in the progress of its discovery was complete.

When the characteristic features of a new disease have once been clearly pointed out, it is remarkable to observe how rapidly cases of it begin to be recognized. In the two or three years which followed the appearance of Leyden's article, numerous cases of multiple neuritis were reported in the journals. And many physicians, reviewing their records, recognized, in cases previously obscure or imperfectly diagnosticated, typical pictures of the new disease. It may be well to consider a few of these cases in order to complete our clinical knowledge of the affection.

Observation VI.—A female, aged thirty, of intemperate habits, but otherwise in good health, after suffering from formication, coldness, and pains in her feet and legs for some months, noticed an œdema of both legs. This increased rapidly after a few days, and the swollen limbs became painful to touch or pressure, and were the seat of severe lancinating pains, which were worse at night. Within a month the same symptoms appeared in the arms and hands, and a marked hyperæsthesia developed in all the extremities, as well as a rapidly progressing paralysis; so that, on admission to the hospital, six weeks after the appearance of the œdema, it was impossible for her to lift her limbs from the bed, or to extend her hands and fingers. The movements in the distal portions of all the extremities were much more impaired than those near the trunk, and in the paralyzed extensor muscles the faradic excitability was almost abolished. Heart and kidneys normal. She had some fever, and was delirious at night. The symptoms increased rapidly; the paralysis became total; respiration became difficult; the heart rapid, and a week after admission to the hospital she died.

Autopsy: Tubercles in the lungs. Brain and cord were normal. Nerve-roots were normal. In the nerves of the extremities marked degeneration was found, especially in the radial and tibial nerves. By the side of a small number of empty sheaths were found fibres, whose myelin was segmented and in drops, separated by empty spaces. The axis-cylinders were indistinct. There was no increase in the nuclei of the sheath of Schwann.

In discussing the case Dr. Lancereaux made the diagnosis of alcoholic paralysis, assigning the lesion to the nerves, and differentiating it from a myelitis or a meningitis. In so doing he criticised the views of Wilks and Lockhardt Clarke, who still considered alcoholic paralysis as a central disease. He cited another case, very similar, of a female aged thirty-three, in which the symptoms were pains, hyperæsthesia, tenderness, paralysis, with atrophy in the extremities, but in which œdema was not so marked and came on quite late in the course of the case. The same lesions were found. To these he added two cases in which the patients manifested the same symptoms, but had never drank. They were both, however, sellers of varnish, and lived day and night in an atmosphere permeated by alcoholic vapor, from which he concludes that chronic alcoholic poisoning can occur by absorption through the lungs—a valuable observation, but hitherto not confirmed.[1]

The following case was reported by Grainger Stewart, together with two other cases which resulted in recovery.

Observation VII.—A male, aged thirty-one, noticed during August, 1880, a weakness of the legs, and during the following month a pain of a prickling character in the legs and feet. These increased in intensity, and in October a similar feeling came on in the fingers and hands, accompanied by loss of power and stiffness. When seen, in November, he had tingling pain in both legs from the knee to the back of the foot, with numbness and feeling of cold in the toes and plantar surfaces, so also in the hands, to a less extent. No girdle pain or formication. Sensibility to touch was diminished in the legs and hands. Transmission of impressions was delayed. Sensibility to heat, tickling, and pain were all diminished, as was also the muscular sense in the feet. There was no nystagmus, although he complained of things dancing before his eyes. Sight was normal. There was no incontinence of urine or feces. The skin reflexes were absent in the soles, but normal in the abdomen and groins. The knee-jerk was absent. Voluntary motion was greatly impaired in legs and arms, and attempts to use the muscles caused pain. Electric irritability of the muscles and sensibility of the skin were much diminished. There were no vasomotor or trophic changes. His mental condition became changed during his stay, his memory was impaired, and he seemed drowsy. A month after his first examination he died of pneumonia.

Autopsy by Dr. D. J. Hamilton: The median, ulnar, and tibial nerves showed great changes. With a low power of the microscope the bundles of fibres appeared to be affected by fatty degeneration. With a high power it was found that the axis-cylinders were swollen so as to form a number of fusiform bodies in the course of the nerve-tubes. These at parts were divided into a number of round homogeneous colloid bodies. When set free these bodies underwent a fatty degeneration, forming compound granular corpuscles. In some fibres the axis-cylinder was totally destroyed, nothing but a quantity of fibrous tissue remaining. The cords of the brachial plexus and the sciatic nerves were normal. Slight evidence of secondary sclerosis in the spinal cord was found in the columns of Goll and in the direct cerebellar columns. Its origin could not be explained.[2]

It must not be supposed, from the fact that all the cases so far cited were fatal, that death is always the result in multiple neuritis. This is very far from the truth, and probably, if the mortality had been greater, the pathology of the disease would not so long have eluded search. The fatal cases have been brought together in order that the pathological appearances observed might be noted and compared, and might become somewhat familiar by repetition. It is time to enter upon the more careful study of their pathology, and so, for a time, let us leave the clinical features of the disease.

It may not be out of place, before proceeding to discuss the changes occurring in inflammations of the nerves, to review the normal anatomy of a nerve.

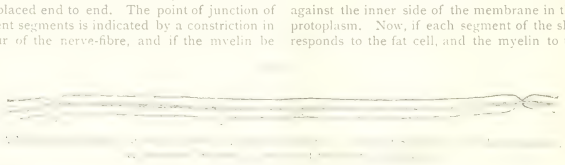
The Histology of a Nerve-Fibre.—When a nerve-trunk is dissected, the connective-tissue sheath or perineurium enclosing its fibres torn away, and the individual fibres set free by teasing from the finer connective-tissue strands or endoneurium which bind them together, it is possible to distinguish certain parts, by means of appropriate methods of staining.

There is *first* the axis-cylinder, Fig. 1 (*a*). This is made up of a number of primitive fibrils arranged longitudinally and continuous throughout the length of the nerve. The fibrils are cemented together by a substance which appears finely granular. Each cylinder is supposed to represent a prolongation of a single nerve-cell; but whether the individual fibrils of which it is made up come from the same cell or from different cells, or from the fibrillary network in the central organ surrounding the cell, is a matter of hypothesis.[1]

There is, *secondly*, the myelin sheath surrounding the axis-cylinder, Fig. 1 (*b*). This is not a continuous tube, but consists of a series of little tubes, or interannular segments placed end to end. The point of junction of two adjacent segments is indicated by a constriction in the contour of the nerve-fibre, and if the myelin be cemented to one another at the point of constriction of the fibre. This constriction is known as the ring or node of Ranvier, Fig. 1 (*d*), and at its situation the sheath of Schwann is the only covering of the axis-cylinder. On the inner side of this sheath, and half-way between two nodes, is found a nucleus (Fig. 1, *f*). The sheath and nodes are made evident by staining with nitrate of silver, while the nucleus is seen best by staining with carmine or acid fuchsin. The mutual relation of the sheath of Schwann and the myelin sheath, are best understood by the study of their development, segment by segment. Ranvier[1] likens the production of any one segment of these sheaths to the production of a fat cell from a nucleated cell. Every nucleated cell is surrounded by a layer of protoplasm. As the fat forms, it collects within the layer of protoplasm in the vicinity of the nucleus, in the form of drops which finally unite into a mass. This mass is surrounded by a very thin layer of protoplasm and by the cell-membrane. On one side of it is seen the nucleus flattened out against the inner side of the membrane in the layer of protoplasm. Now, if each segment of the sheaths corresponds to the fat cell, and the myelin to the fat, the



stained with osmic acid it is seen to be deficient at these constrictions. If, by any means, the nerve-fibre be broken, the myelin in any segment will run out and collect in drops, showing that it is a semi-fluid substance, of fatty nature.[2]

There is, *thirdly*, a connective-tissue membrane surrounding the myelin sheath, the sheath of Schwann, Fig. 1 (*e*). This, like the last, is made up of segments

structure of the segment is clear. The membrane of the fat cell is represented by the sheath of Schwann. At the point of constriction of the nerve-fibre this membrane is cemented to that of the adjoining segment. Beneath the membrane, and flattened against its side, is the nucleus of the segment, lying in a layer of protoplasm in the middle of the segment. This layer of protoplasm forms a lining everywhere to the sheath of Schwann. With that sheath it is reflected around the axis-cylinder. Within the lining, in a state of semi-fluidity, is contained the myelin, which will run out if the limiting membrane is broken. By appropriate staining fine lines can be seen passing between the outer and inner layers of protoplasm, through the myelin sheath, the so-called incisions of Schmitt, Fig. 1 (*e*). These have been considered little trabeculæ of protoplasm within the segment in the midst of which the myelin lies. Recent staining methods seem to indicate that they belong to the sheath of Schwann and are connective tissue. The layer of protoplasm lying against the axis-cylinder, is the layer which was formerly described as the sheath of Mauthner. Some authorities consider that a layer of connective tissue similar to the sheath of Schwann surrounds the axis-cylinder, but this is still uncertain. Thus the nerve-fibre consists of a central conducting strand, surrounded and insulated by a series of tube-like segments of fluid contained within a membrane, which are joined to one another, forming a double protecting sheath.

Individual fibres are associated in bundles held together by fine connective-tissue cells whose nuclei

[1] Ranvier: Leçons sur l'Histologie du Système Nerveux, tome

[1] Without their [illegible] is certain that they pass together in the axis-cylinder to the periphery, and that there the axis cylinder as such terminates, while the individual fibrils branch out in various directions, and, joining with other fibrils from other cylinders, form a fine plexus within the organ to which the nerve as a whole has gone. It has been thought possible to trace individual fibrils of the plexus into individual epithelial cells. Such is their termination in various internal organs, and in the skin. This is not, however, the only manner of termination of the axis-cylinder, for individual nerves can be traced directly to terminal organs, such as the terminal plates upon the muscle, and the terminal bulbs and corpuscles in the skin; in which cases no division or branching of the fibrillary constituents of the axis-cylinder has been discovered. The termination in each of the organs of special sense is still different. The axis-cylinder can best be seen by the acid fuchsin stain.

[2] The myelin sheath is not a necessary constituent of all nerve-fibres, for the majority of the nerves of the sympathetic system are devoid of such sheaths. Nor does the myelin sheath of the nerves of the cerebro-spinal system extend from end to end of the axis-cylinder. For the axis-cylinder first receives its sheath at some little distance from the cell from which it issues, and at its termination, where it breaks up into branching fibrils, the myelin envelope ceases. Throughout the course of the nerve, however, the myelin sheath is present in the cerebro-spinal nerves, forming a protecting envelope, and probably acting as an insulating sub-

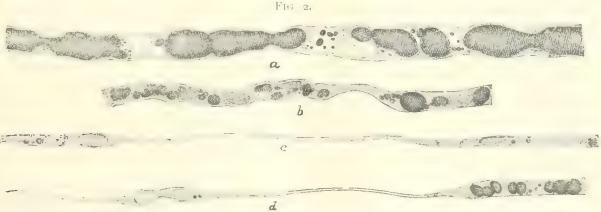
can be seen in a carmine or fuchsin stained preparation, lying always adjacent to, but outside of, the sheath of Schwann.[1] This has been called the endoneurium, while the connective-tissue sheath surrounding the entire bundle is named the perineurium. Capillary vessels with free anastomoses run within the nerve, their walls lying adjacent to the individual fibres, and thus affording a perfect nutrition.[2] Lymph-spaces also have been demonstrated within the nerve sheath, but not among the fibres.[3] That the interfibrillary spaces of the endoneurium, however, open into these perifascicular lymph-spaces is probable, from the fact that they do so in other organs. While it is evident that the nutrition of the axis-cylinder is derived from the circulatory fluids, it is probable that it is only at the nodes of Ranvier that the absorption takes place, since elsewhere the myelin sheath interferes with osmosis. Thus, if the nerve be put in nitrate of silver, it is only opposite the nodes that the axis-cylinder becomes stained.

The Pathology of Multiple Neuritis.—In studying the pathological processes which occur in multiple neuritis, it is necessary to keep these various elements of the normal nerve in mind, since each element is subject to changes. The exact character of these changes is best understood by observing the results of nerve-correspond quite exactly to those produced by experimental degeneration.

In considering the pathology of degenerative neuritis we enter at once upon a mass of controversial statements. It would seem to be a simple matter to establish, by observations upon nerves which had been experimentally compressed or severed, the changes which ensue in nerve injuries. But, as a matter of fact, there is, perhaps, no field of experimental pathological inquiry in which the results have differed more widely. In the first place, it is probable that the rapidity and even the character of the changes differ in different animals. Secondly, various methods of investigation, of hardening, dissecting, and staining the nerves, seem to have resulted in the production of different appearances. And, lastly, it is by no means certain that a uniform pathological process goes on after experimental lesions.

After a lesion of a nerve-trunk, a process of degeneration sets in at the point of injury, and involves a small portion of the central end and the entire peripheral part of the nerve, from the seat of injury onward. This process may be more or less complete, and may, or may not, be followed by a second process of regeneration in the diseased nerve. It is necessary to distinguish between the degenerative and regenerative processes; and, inasmuch as it is affirmed that they may proceed

FIG. 2.



The Process of Degeneration (after Ranvier). *a*, Segmentation of myelin and axis-cylinder, with increase of protoplasm; *b*, disintegration of myelin into drops, increase of nuclei, partial absorption of débris; *c*, complete absorption of the disintegrated mass, leaving the Schwann sheath empty, or containing only débris and nuclei; *d*, the same, nuclei alone remaining.

degeneration artificially produced in animals. And a study of this will not be out of place here, for, as we shall see, the changes occurring in multiple neuritis simultaneously in various parts of the same fibre,[1] it is not strange that the confounding of the two should have increased the confusion in the statements.

In early times it seems to have been a question whether the destruction of a nerve was ever recovered from, and while the majority of authorities rightly contended that this was possible, there were those who denied it vehemently. Steinneck,[2] in 1838, seems to have determined this fully in the affirmative, using both the physiological and anatomical data at his disposal to good advantage. The exact processes of degeneration were first carefully studied by Nasse[3] and Waller,[4] and their results having attracted attention to the phenomena in question, a host of investigators have followed their lead. The most careful examinations of the entire series

[1] These connective-tissue cells which lie between individual fibres, have been recently the subject of study by Adamkiewicz (Adamkiewicz: Ueber Rückenmarkschwindsucht. Sitzungsbericht der Wiener Acad., Bd. 91, Abth. II.), and Rosenheim (Rosenheim: Arch. für Psych., xvii. S. 820). The former regarded them as nerve-corpuscles, but the latter has proven that they are true connective-tissue cells. They are best seen in specimens stained with a double staining of anilin gentian-violet, and methyl-blue, though they can be seen distinctly in fuchsin stained preparations, as has recently been demonstrated by Dr. Van Giesen, of the Laboratory of the College of Physicians and Surgeons. They appear on nerves after the age of five, and increase in number as the individual grows older, so that in elderly persons they are very numerous. They are round or spindle-shaped, and frequently appear to have little thorn-like processes. In addition to these connective-tissue cells there are fine fibrils of connective tissue, and bands of tissue lying between the bundles of nerve fibres.

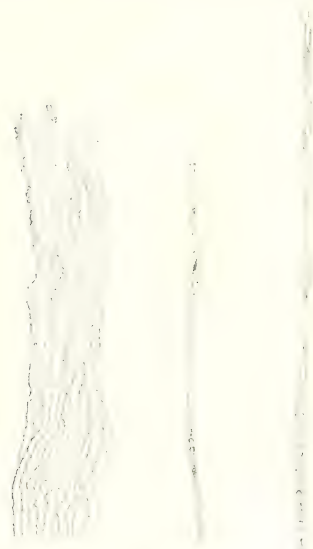
tion have been made by Ranvier,[1] Phillipeau and Vulpian,[2] and Dejerine,[3] in France; by E. Neumann,[4] S. Mayer,[5] and Wolberg,[6] in Germany; by Hanken,[7] in [illegible] by Weir Mitchell,[10] in America.

The majority of writers upon nervous diseases, and upon general pathology, seem to have followed Ranvier closely, without any mention of the fact that other



authorities differ from his conclusions. It will be necessary here to present the various views which are held.

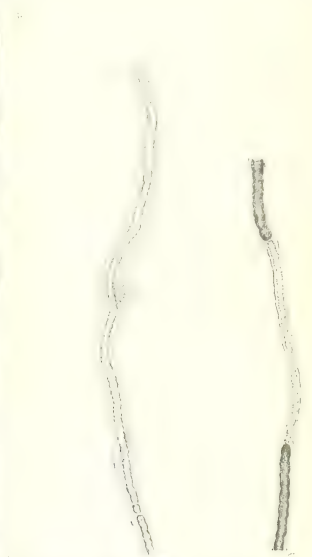
The Process of Degeneration.—When a nerve is compressed by a ligature, or forceps without sufficient force to rupture the sheath of Schwann, the myelin is driven away from the point of pressure in both directions, and the axis-cylinder is disintegrated and mingled with it. It might be supposed that the nodes of Ranvier would prevent such a driving back of the myelin, but they seem to offer but feeble resistance, so that the entire fibre on either side of the compressed spot is bulged out



[illegible] Nerve [illegible] *a*, Segmentation of the myelin; [illegible] *aa*, reduced to granular mass; *c*, sheath of Schwann, containing oil [illegible] in [illegible]; *d*, granular

for some little distance, the sheath of Schwann between the distended portions being left empty, or containing only a little granular débris. In a short time changes of a degenerative character are observed on both sides of the point of compression. Those on the central side are limited to the immediate neighborhood of the injured spot, and, according to Ranvier, do not affect the nerve for a distance greater than a centimetre from the point of compression.[1]

[1] Some recent investigations of Friedländer and Krause throw doubt upon this statement. (Fortschritte der Medicin, Dec. 1886. They have discovered a considerable degree of atrophy in the nerve-trunks in the stumps of amputated extremities, and they traced this atrophy upward through the nerves, and into the pos-

On the peripheral side of the point of pressure the degeneration is extensive, involving the entire nerve down to its finest terminations. The process is held by some to be a gradually advancing one along the fibre from the point of pressure outward, while others believe that it begins at once in the entire length of the nerve. The first change noticed is a breaking up of the myelin sheath into segments, and then into smaller masses and drops (Fig. 2, *a*, *b*), which finally undergo further disintegration, either by a fatty or albuminoid degeneration, or by a process of saponification, until a finely granular mass alone remains. Tizzoni states that this process is partly due to the activity of migratory white blood-globules, a view which Ranvier supports, and which Neumann and Mayer deny. If, as seems probable, the connective-tissue cells of Rosenheim take an active part in all processes of nerve inflammation, it is possible that these are the bodies which Tizzoni mistook for leucocytes. Ranvier holds that the segmentation of the myelin is due to the increase of the protoplasm about the nucleus of the segment, and that it is this protoplasm which replaces the myelin. Neumann holds that the granular mass resulting from the disintegration is not protoplasmic, but is a débris capable of acting as the basis for processes of regeneration after undergoing a chemical change. All authorities admit that the granular mass may be gradually absorbed, leaving the sheath of Schwann collapsed and empty, or containing only granules of débris (Fig. 2, *c*).

As the myelin undergoes these changes the axis-cylinder usually becomes involved. Some authors, it is true, believe that it remains intact, and that, although deprived of its function, it is capable of resuming that function at any time when regeneration of the myelin sheath has taken place. Such authorities as Erb, Charcot, Weir Mitchell, and Wolberg have given their approval of this view. Ranvier believes that the protoplasm of the nucleus attacks and destroys the axis-cylinder as well as the myelin. Neumann holds that it is split up into segments like the myelin, becomes mingled with it, and undergoes the same process of chemical change, or absorption; and Mayer agrees with this view. (Fig. 3, *a*, *b*, *c*.)

The sheath of Schwann also takes part in the process of degeneration. When that process has fairly begun numerous nuclei are observed lining this sheath in each interannular segment. They may have come by a process of segmentation of the original nucleus of the segment, as Ranvier holds. But Neumann and Mayer have shown that they appear as early at the extremities of the segment as they do in the vicinity of the nucleus, and they therefore conclude that they are a free formation originating in the granular or protoplasmic mass. Tizzoni thinks them emigrated corpuscles. The most recent view of all is that of Rosenheim, that they come from the connective-tissue cells along the sheath which divide and multiply, and show powers of emigration as soon as the process of degeneration begins. When the granular mass is absorbed these nuclei remain scattered along the sheath of Schwann, and it has been suggested that, when in an empty sheath a new axis-cylinder appears, it owes its existence to these nuclei, which arrange themselves in a line, and develop into the new fibre (Wolberg). If no regeneration occurs they disappear gradually, and then the only relic of the former nerve-fibre is the empty, collapsed sheath of Schwann, which remains as a connective-tissue strand.

The increase of nuclei and connective-tissue fibrils in the endoneurium and perineurium which accompanies the process of degeneration, aids in the transformation of the nerve into a band of connective tissue.

The degeneration which affects the nerve is continued to the terminal plates upon the muscle, and these are changed into a mass of granules and finally absorbed, a connective-tissue plate being left.[1] Whether any changes occur in the sensory terminal organs, such as the tactile corpuscles or terminal bulbs, has never been ascertained. Those who believe that the individual axis-cylinder fibrils terminate in the epithelium of the skin may cite the trophic changes which often occur on the surface as evidence that this covering of the body shares in the nerve changes.

Authorities seem to agree that the same results follow a division of a nerve that are observed after its compression, with the difference that at the point of section the myelin runs out of the sheath of Schwann. The cut end of the nerve becomes swollen into a bulbous extremity by a growth of connective tissue.

Whether a true union of the divided ends ever occurs is still a matter of uncertainty. The majority of authorities, following Ranvier, affirm that while a primary coaptation of the ends by an exudate which is secondarily transformed into connective tissue, may occur and hold the ends in position, no true primary union of nerve-fibres is possible, and under all circumstances the degenerative process already described goes on to completion. Glück, however, claims to have observed an actual union of the two ends, with reëstablishment of function, at a time too early to have admitted the occurrences of degeneration and regeneration; and Wolberg, approaching the subject from the surgical side, and considering the results of nerve-suture, inclines to the same view.

In the midst of such contrary statements, what conclusion can be reached as to the actual facts? It seems evident that but one conclusion is certain, viz., that under different circumstances different processes occur. The various observers are equally trustworthy. It is impossible to choose one set of conclusions rather than another, or to rely wholly upon one series of experiments, however capable the observer may be, for they all rest upon repeated observations. It is undoubtedly

terior nerve-roots exclusively. They conclude, therefore, that the fibres affected are entirely sensory fibres. The axis-cylinder is only slightly affected by the atrophy, but the myelin sheath is wholly destroyed. Inasmuch as the degree of atrophy in a nerve-trunk was about the same, whether the amputation had been made near the body or near the end of the limb, they conclude that only certain of the sensory fibres degenerate upward. And as the tactile corpuscles and terminal bulbs are found only in the most distal parts of the extremities, it is suggested that only those sensory fibres degenerate which arise from these so-called tactile bodies. If this is proven to be true by further observation, the tactile bodies will assume the *rôle* of trophic centres for the sensory nerves. And in this case anything which interrupts the connection between the tactile bodies and the posterior spinal ganglion will produce a centripetal degeneration in the nerve. Hence in neuritis from section or pressure, as well as in multiple neuritis, such secondary degeneration is to be expected and should be looked for.

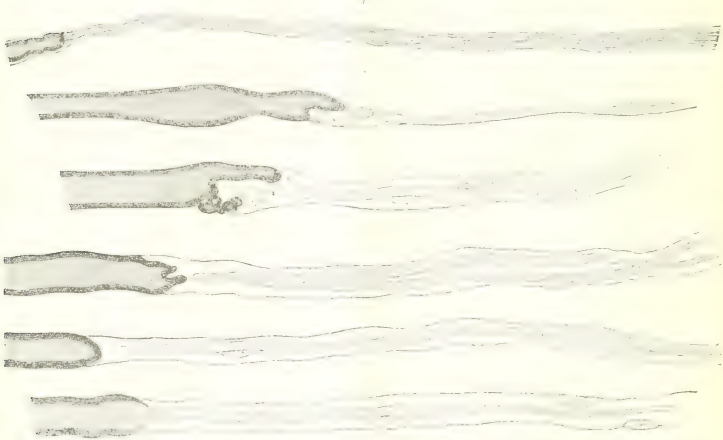
[1] Gessler: Die Motorische Endplatte und ihre Bedeutung für die Periphere-Lahmung. Leipzig, 1885.

true that in some cases the degenerative process, so graphically pictured by Ranvier, from the beginning segmentation of the myelin down to the final result in the connective-tissue strand, the relic of the empty sheath of Schwann, goes on; while, in other cases of a less serious nature, the destruction is less complete, and there remains a fibre consisting of a sheath of Schwann, containing a granular mass which may be either an axis-cylinder, or a mass capable of developing into an axis-cylinder under favorable circumstances. If this is the case, we can affirm that brilliant surgical successes, with rapid restoration of nerve function after suture, are possible when the partial degeneration is present, but are impossible when the total destruction of the nerve-fibre has occurred. And statistics show that there is a certain percentage of operations which fail of any result, though repeated on the same nerve.

widely divergent views are held. Ranvier[1] and his followers claim that the new nerve is wholly a product of the central end of the injured nerve, growing out from it and making its way along the track of the peripheral end, which takes no active part in the process. Neumann and Mayer, on the contrary, believe that the regeneration goes on in the peripheral end of the cut nerve, segment by segment being formed successively, beginning at the point of injury and proceeding outward, the entire nerve being built up by the union of each distal segment, with the one lying centrally to it, until this process has reached the end. These various views demand a more exact statement. (Fig. 4.)

Ranvier describes several ways in which the new fibres issue from the central end. He has seen the central end of an individual nerve-fibre become hypertrophied, and from this swollen part a single new fibre start out al-

Fig. 4.



y nuclei; *c*, ditto, with increase of protoplasm destined to become a new myelin sheath, overlapping of old myelin upon the new; [illegible] new fibres developing [illegible] one in advance of the peripheral one; *f*, final union of the peripheral with the central segment, nuclei still remaining.

It is evident that future research should be directed, not so much to determine which of the processes described occurs, as to settle under what circumstances the one is produced rather than the other. And such research will have an eminently practical bearing, inasmuch as it will also demonstrate under what circumstances nerve-suture is likely to be attended by success.

The Process of Regeneration.—After the process of degeneration has gone on for some time in the nerve-fibre, it may cease, and the process of regeneration may begin. With regard to the method of this process two ready medullated. He has also seen a single axis-cylinder grow out, and then divide into two, or even more, axis-cylinders, each of which develops into a complete medullated nerve. Or from the swollen central end of a single fibre several medullated and segmented fibres may originate, or one medullated fibre may be sent out with several non-medullated fibres coiled about it; or, lastly, a simple axis-cylinder branches out without a medullary sheath, divides into

[1] Loc. cit., ii. 42-67.

two, and each of these in turn divides into two, and so on, until the sheath of Schwann, which had originally but one axis-cylinder within it, contains as many as eight or more (Fig. 4, *a*). These new fibres appear like a brush upon the end of the divided nerve, and wind about each other, forming a sort of plexus. By the aid of the cicatricial tissue, which usually joins the central end with the degenerated peripheral end, the bushy, branching fibres are directed outward toward the periphery. And when they reach the peripheral end of the cut nerve they insinuate themselves into the old remaining sheaths of Schwann, or between those sheaths, and grow on and outward till at last they reach the termination of the peripheral end, and the regeneration is complete. The terminal plates upon the muscles are renewed by a production of protoplasm in the plate. The description given by Neumann and Mayer is very different. It will be remembered that they describe, as a result of the process of degeneration, a band of fibres each consisting of a sheath of Schwann containing a granular mass. The process of regeneration begins in this mass. Within it they have seen a narrow band of fine homogeneous substance appear, which has the structure of a rudimentary axis-cylinder (Fig. 4, *b*). This does not fill the sheath of Schwann, and is often pressed aside by the nuclei which lie in that sheath (Fig. 4, *c*). It is not at first continuous with the end of the old axis-cylinder, remaining in the central part of the compressed or divided nerve, but as it increases in definite structure it approaches this old axis-cylinder, and finally unites with it. At the point of union a ring of Ranvier is formed. As this axis-cylinder develops, a substance is gradually formed around it, which is stained by osmic acid. This increases in thickness as the protoplasmic mass and the nuclei diminish, until it finally forms a new myelin sheath. The new myelin sheath is never continuous with the old one in the central end of the nerve, since it is separated from that by the ring of Ranvier; but often at first the older sheath seems to bulge out and encircle the new sheath, though this appearance is never permanent (Fig. 4, *c*). At the point of union of the new fibre with the old one, nuclei are often found; but these, like the others, gradually disappear (Fig. 4, *b* and *d*). Lastly, a new sheath of Schwann is produced around the new myelin sheath, and within the old sheath of Schwann. It presses aside the old sheath, together with such masses of protoplasm, drops of myelin, and nuclei as may remain, leaving them thus wholly outside of the new-made fibre, so that they coalesce with, and make part of, the endoneurium. The new sheath of Schwann has but one nucleus in each segment, and presents the nodes of Ranvier at regular intervals.

Neumann has shown that this process goes on in every individual segment of the nerve-sheath, so that in segment by segment, proceeding toward the periphery, the regenerative changes occur, and as each segmen approaches completion it joins itself to the preceding one (Fig. 4, *e*), until finally the entire nerve is reëstablished in its entire length. As the degenerative process begins in the segment nearest to the point of compression, so does the process of regeneration; and in some nerves the two processes may be seen going on together, the segments near the seat of injury being renewed while those at the periphery are still in a state of degeneration. The new fibres do not grow out from the old ones, as Ranvier describes in the regeneration of cut fibres, but protoplasm, with specific developmental properties, forms and differentiates the elements of the new fibre, and then unites it to the old one. The new fibres are, at first, somewhat smaller in calibre than the old ones (Fig. 4, *f*), but they gradually attain a normal size, and then the process may be said to be completed.

While Neumann would have the new fibres develop from the granular mass remaining in the old sheath of Schwann, Gunther, Hjelt, and Weir Mitchell suppose that they may originate from the nuclei of the old sheath, or even from connective-tissue cells and neurilemma nuclei remaining in the connective-tissue strand, and to this opinion Wolberg agrees. It is evident, therefore, that the process of regeneration is by no means accurately determined. But here again it is possible that conflicting statements may be explained. The method of regeneration may, perhaps, depend upon the exact stage of degeneration reached before it begins. If the product of degeneration is a simple band of connective tissue, it seems probable that the nerve-fibre will have to grow into it from a central origin, as in its original development in fœtal life, unless the connective-tissue cells recently discovered are neuroplastic cells, and have the power of producing new nerves, just as cells of periosteum may produce a new bone. If, however, when degeneration ceases, there remains a sheath of Schwann containing a granular protoplasmic mass, it is not at all improbable that that mass may be differentiated into an axis-cylinder and a medullary sheath, and joined to the old nerve-fibre, a process which has its analogy in the medullation of nerves in the embryonal state. If we admit, with Wolberg, that in some cases the axis-cylinder is not destroyed, the formation of new myelin is a rapid matter. That some such process as the one last described must occur in certain cases is certain, when the rapid recovery after minor injuries is considered, and when the results of nerve suture are taken into account; for in both these conditions the return of function occurs long before a new nerve-fibre, starting out from the old one, could have reached the periphery.

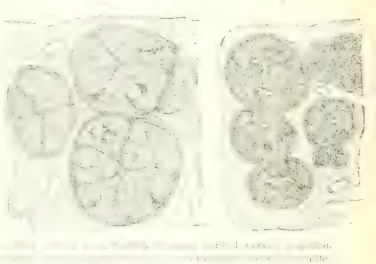
It is affirmed by Mayer that individual nerve-fibres in normal nerves are constantly undergoing these processes of degeneration and regeneration, either because the necessary renewal of worn-out tissue takes place in this manner, or because slight injuries from pressure or over-strain are sufficient to start up degeneration in single fibres.

The process of degeneration in the nerves, consequent upon the destruction of the ganglion cells from which they arise (the so-called Wallerian degeneration) differs in no respect from that ensuing upon compression or division, excepting that in the latter case only the distal part of the divided nerve undergoes the pathological change, while in the former it is the entire nerve that is affected. And in the changes described in multiple neuritis the same progress of events and the same varieties of termination are observed.

When the cases of multiple neuritis are examined from a pathological standpoint several varieties may be distinguished. In some of the cases, and these are the most numerous, there is a parenchymatous inflammation in the nerve-fibre only visible to the microscope.

At the outset of this inflammation the myelin sheath appears slightly swollen, is less homogeneous, and, from a difference of refractive power, is less translucent. It then becomes split up into segments of different length and form, the segmentation occurring preferably at the incisures of Schmitt, while the incisures at other parts disappear. Between these segments of myelin, a finely granular protoplasm is seen, in which new nuclei are found. These nuclei probably are the cells of Rosenheim which have emigrated, although a few near the nucleus of the sheath of Schwann may be due to its division. In some fibres the axis-cylinder may still be preserved. In others it is broken at the same places as the myelin. At the next stage of the process the changes are more marked. The myelin is now reduced to a series of small globules surrounded everywhere by granular protoplasm, and in this protoplasm the nuclei are now very numerous. The axis-cylinder cannot be distinguished in the mass, as a rule, but occasionally a fine line is seen passing through the mass, which may be a remaining cylinder. The succeeding stage presents a different picture. While up to this time the size of the nerve-fibre has remained about normal and uniform, it is now seen to vary. At places the fibre is still wide and filled with a granular mass, at other places it is narrow, the mass having disappeared, leaving either a collapsed sheath or a sheath containing only nuclei here and there. In a few such narrow fibres there seems to be an axis-cylinder lying directly within the sheath of Schwann, and occasionally separated from it at various places by nuclei. But this appearance is rarely seen. As a rule, no trace of the axis-cylinder remains. As any single fibre may show at some places constrictions, at others dilatations, the variation in its calibre is the most striking feature of this stage. In the terminal stage the calibre is uniform again, but is now everywhere reduced. The sheath of Schwann is empty, or contains only a little granular substance, and the nuclei are now less numerous than before. There is, in fact, only an atrophied tube with none of its original contents. These tubes lying side by side are folded and undulating, and appear like a strand of connective tissue.

These various stages of parenchymatous inflammation are to be seen in different fibres in the same specimen. Their appearance is identical with that observed in the course of degeneration of a nerve after compression, or after destruction of the spinal ganglion-cells. This has led such an accurate observer as Erb to advance the hypothesis that some slight changes in trophic cells in the spinal cord, not visible to the microscope, are present primarily, and that these changes are of a secondary nature.[1] But this cannot be admitted. Those who would explain the parenchymatous neuritis as secondary to changes in the cord, fail to explain why it should be limited, as it is, to the distal portion of the nerves, and not be continuous through the nerve-trunks, and anterior nerve roots into the anterior cells. They also offer no explanation for the cases in which the sensory, as well as the motor, nerves are affected, centrifugal degeneration of these nerves from spinal lesion being unknown. Strümpell, in meeting Erb's hypothesis, urges with reason that a parenchymatous neuritis has its parallel in other parenchymatous inflammations, and therefore does not need to be traced to any primary affection in trophic cells. He also mentions the existence of primary lateral sclerosis of the cord, similar in all respects to secondary degeneration of the pyramidal columns—yet now admitted to be a primary disease—as illustration of the fact that like changes are not always to be traced to one cause. It cannot but be admitted, therefore, that the first class of cases of neuritis must be considered as due to a primary parenchymatous inflammation in the nerve-fibres. This form seems to be much more frequent in its occurrence than the first variety, and constitutes the lesion in the majority of the cases hitherto reported. The appearance in section is seen in Fig. 5, *b*. The appearances of single fibres are the same as those shown in Figs. 2 and 3.



reduced in size, individual fibres degenerating, their place taken

A second class of cases presents a different appearance.

In this class the mere inspection shows the nerve to have been the seat of pathological changes, for it is either congested, swollen, and lacking in lustre, or it is yellow and irregularly swelled by the accumulation of fat, or it is evidently reduced to a mere connective tissue strand. Upon teasing the nerve it is at once clear, from its brittleness, that individual fibres are lacking in continuity and are changed in structure. And if it is examined under the microscope the exudation of serum, and of lymphoid bodies, the great increase in the number of connective tissue nuclei, the distended condition of the vessels, as well as the various appearances characteristic of nerve degeneration, are clearly seen. Here the inflammation is either originally an interstitial inflammation, or, more probably a diffuse one. It is possible that the degenerative processes in the nerves may have been due to the compression by the exuded products of inflammation within the nerve-sheath. In one or two cases where the patient died early in the disease, the nerve-fibres which lay near the vessels were affected to a greater degree than those lying deeper, and from this fact it was concluded that their degeneration was secondary. In other cases, however, all the fibres in a bundle are equally involved. Here it is probable that the inflammation was diffuse from the outset, paren-

chyma and interstitial tissue being affected simultaneously. The final result in either case is a diffuse inflammation. One marked feature in these cases is the large amount of fatty deposit found in the altered nerves. This is to be ascribed to the fact that myelin in undergoing degeneration breaks down into globules, and undergoes a fatty change. It is itself allied to fat, and making up, as it does, a large part of the bulk of the fibre, it would be noticeable in the product of degeneration if it were not absorbed. In this form the absorption seems to be interfered with by the vascular condition, and hence the residual amount of fat is increased. The changes observed in the nerve-fibres are very similar to those seen in the first form of neuritis, and need not be described again.

It is to be noted that in both of these forms the pathological changes are always more intense in, and are occasionally limited to, the peripheral terminations of the nerves. The nerve-trunks may be slightly involved in their distal portions, but it is very rare to find any changes in them at their origin from the plexuses. And, as a rule, the spinal nerve-roots in cases of multiple neuritis are normal. In making autopsies upon such cases this fact is to be remembered, and the nerves are to be removed down to their finer branches in the muscles and fascia.

One additional pathological form must be mentioned, since it has been described by such a careful observer as Gombault.[1] It is the so-called segmental periaxillary neuritis. In toxic neuritis from lead-poisoning, Gombault found that the degenerative process was not uniform in the entire length of the nerve-fibre. On the contrary, entirely normal segments alternated with the degenerated segments in the nerve. Mayer has noticed a somewhat similar condition (Fig. 3, *e*). The changes already described take place in the myelin sheath of the affected segment, even to its entire absorption, leaving the axis-cylinder in the sheath of Schwann. But as the adjacent segments are not involved, regeneration is thought to be more easily accomplished. Pitres and Vaillard[2] have noticed a somewhat similar condition in the neuritis occurring after diphtheria, although in their case the axis-cylinder as well as the myelin sheath was totally destroyed in many segments.

While it is, of course, impossible to describe definitely the process which goes on to complete regeneration of nerves in multiple neuritis, there is no reason to suppose that it differs in any way from that observed in experimental lesions.

The time required for the completion of the process will depend upon the severity and extent of the degeneration. When that is slight the recovery may be rapid, cases having been reported where a total cure took place in two months. As a rule, however, it is a slow process. The large majority of the cases on record required over six months for the complete regeneration, and in not a few cases from ten to sixteen months elapsed before the condition of the nerves was proved to be normal by the total disappearance of all symptoms.

With the end of 1883 we may consider the third stage of pathological discovery in the history of multiple neuritis as terminating. At that date the symptoms of the disease had been recognized as constituting a distinct clinical picture; hypothetical lesions in the spinal cord had been abandoned, and the exact pathology of the disease had been ascertained. Since 1883 the final period in the development of knowledge of the affection has been in progress. About one hundred cases, of varying degrees of severity, have been observed (see bibliography). The lesions described have been confirmed in all their details. The symptoms arising in the course of the disease have been subjected to careful analysis, together with their varied modes of combination. Certain diseases hitherto considered of spinal origin, are found to be due to peripheral disease. Thus it has been discovered that a form of ataxia may occur from multiple neuritis of alcoholic or arsenical poisoning, which closely resembles and was formerly confounded with tabes; also, that some cases supposed to be anterior poliomyelitis must now be differently named. And as physicians review their records, they find that former diagnoses require revision in the light of new discoveries, and that greater circumspection is to be exercised in differentiating spinal from peripheral affections. The grounds for such differential diagnosis will require attention in the next lecture. And, what is perhaps of greater importance, the fact has been elicited that some combinations of symptoms formerly supposed to be without a pathological basis, some of the so-called peripheral neuroses, really belong to this class of diseases. At present we have only time to allude to one or two forms of peripheral neuroses which must be removed from that unsatisfactory category of disease and be considered as peripheral neuritis.

And the first of these is the affection termed numb-fingers. This was first described by J. J. Putnam, of Boston, but met with instant recognition from neurologists, and from general practitioners all over the world. It is a disease chiefly seen in women between the ages of forty and sixty, usually associated with dyspeptic or uterine symptoms, but entirely independent of them. It begins as a tingling sensation in the ends of the fingers, felt at night, and sufficiently annoying to keep the patient awake. It then extends to the entire fingers, and may invade the hand, and is felt by day as well as by night. The fingers are so numb that all finer acts become impossible; the patient can no longer sew or knit, cannot be sure of holding anything securely, and finds herself unable to perform any delicate movement. Sometimes a slight degree of anæsthesia and analgesia can be discovered by ordinary tests, but often the disturbance of sensation is purely subjective. There is rarely any incoördination, and paresis is usually wanting. It may develop in the feet as well as in the hands, making walking more or less disagreeable, and adding to the discomfort of the patient. The affection is of indefinite duration; often subsiding quickly under treatment, sometimes baffling all attempts to arrest it. For a time it was considered a purely functional affection, then a spinal cord disease; but now, in the light of the parallelism between the symptoms mentioned and those which are characteristic of multiple neuritis, we cannot but consider it a slight form of this disease.[1]

[1] Ormerod: St. Bart. Hosp. Rep., 1883, Sinkler: Phil. Med. Times, 1885.

The second of the peripheral neuroses which must be referred to peripheral neuritis is intermittent paralysis. Cases of sudden paraplegia, lasting a few hours and passing off as rapidly as they appeared, have been observed too frequently to admit of any doubt. Westphal has described such a case in which no cause could be found. Gibney reported some cases presumably due to malaria. Others have thought the disease of functional character, either central or peripheral. But in the light of recent observations upon infectious cases of multiple neuritis it becomes evident that these sudden, transient paraplegiæ find their adequate explanation in such an affection.

And, lastly, there are numerous cases of indefinite nervous symptoms, pain of various kinds, formication, and odd sensations grouped under the indefinite term numbness, flashes of cold and heat accompanied by actual changes in the temperature of the part, or only by apparent vascular irregularities, slight spasms, or tremors; functional weakness, with sense of fatigue not reaching the grade of paresis, and many equally obscure manifestations of disturbed function in various parts of the body, which receive their best explanation in the theory of multiple neuritis.[1]

Since it was one of the objects of the founder of this lectureship to determine the true nature of such peripheral neuroses, it is with the greater interest that we examine the disease to which they must be assigned.

In the present stage of progress in the history of neuritis much attention is being given to the etiology of the disease. Cases which, from their causation, were formerly separated, are now found to be closely allied in their pathology. Thus the forms of paralysis occurring after the ingestion of various poisons, such as arsenic, lead, and alcohol, are known to be due to a common pathological change. The various kinds of sensory and motor disturbance occurring as complications of the acute diseases, diphtheria, variola, typhoid and typhus fevers, and severe malarial fever, are traced to a lesion in the peripheral nerves. Tuberculosis is known to predispose to neuritis, and many cases formerly supposed, without question, to be produced by central or meningeal affections of a tubercular character, are now assigned to a peripheral cause. It is a question whether syphilis will cause a simple degenerative neuritis, but syphilitic affections of the nerves are easily recognized and well known. Nor can the nervous system escape the action of those microörganisms which are now recognized as the constant cause of many diseases. There is an epidemic form of multiple neuritis, fortunately not prevalent in this country, but occasionally imported here in the form of sporadic cases, known as kakke, or beri-beri, the bacillus of which has recently been discovered and cultivated. And, lastly, there is a class of cases, of supposed spontaneous origin, in which cold or overexertion are assigned as causes, but which need further investigation in regard to their etiology.

It is evident from this array of causes that several conditions formerly separated from one another because of the different circumstances of their occurrence are really forms of the same disease. But while they may be brought together upon a pathological basis, and while all have many symptoms in common, each of the forms of neuritis presents certain distinct features. Without dwelling too long upon any single variety, it will be necessary to review the different classes of cases in order to obtain a clinical picture of each. And such a review, together with the analysis of the symptoms of multiple neuritis, the discussion of its diagnosis from other diseases, its prognosis, and the treatment, will occupy us at the next lecture.

ORIGINAL ARTICLES.

A NEW METHOD OF TREATING CHRONIC AURAL CATARRH.

By RALPH W. SEISS, M.D.,

[illegible]

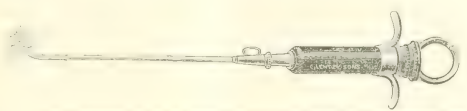
While engaged in the study of the pathology of naso-aural catarrh during November and December, 1885, my attention was particularly drawn to the persistency of certain conditions of the pharyngeal mouth of the Eustachian tubes, as important factors in the general disease. Three principal forms of inflammatory disease of the tubes were noted: 1st. A condition of turgescence and inflammatory infiltration, the tubal lips appearing red and swollen, and secretion from the tubal glands being very active; the nasal pathological condition in these cases was hypertrophic catarrh in the stage of chronic venous distention with infiltration. 2d. The condition here noted accompanied advanced hypertrophic nasal catarrh, the turbinated bodies being largely converted into fibrous tissue. The prominence at the mouth of the tube was here found to be hypertrophied, the color was a dull reddish-yellow on the inferior and bright red on the superior surface. The pharyngeal tonsil was found to be enlarged, and the posterior nares more or less blocked with posterior hypertrophies. In these cases the mouth of the tube was frequently found completely filled with tenacious mucus. 3d. The third condition noted accompanied atrophic rhinitis, and here the lips of the tube were shrunken, the mucous membrane undergoing sclerosis, and the tubal mouth was often blocked by dried crusts.

It was found that after prolonged treatment of the nasal affection had partially or wholly cured the intra-nasal disease, that although the inflammatory conditions present in the Eustachian tubes might be improved, they were rarely if ever cured, the disease persisting in the last half inch of the tube.

Applications made directly to the tubal mouth with the post-nasal applicator or atomizer also gave but slightly better results. Various methods of treatment were tried without avail: the older methods of injecting solutions through the ordinary Eustachian catheter into the canal and middle ear were not tried, the evil effects of these applications in causing acute otitis media and severe inflammation high up in the tube being now well demonstrated.

With the object of making applications to the tube alone without danger of the fluid being forced into the middle ear or high up in the tube, I have devised the following instrument. It consists of an Eustachian catheter closed at the point, and having

the sides of the curved portion perforated with numerous very minute openings. A small syringe is fitted with a metallic nozzle fitting on the ground joint principle into the end of the catheter. The instrument may be made of German silver, but is better made of pure silver. The best average diameter is that of an ordinary Eustachian catheter—three to four millimetres—and the length is about the same, from fourteen to sixteen centimetres. The instrument is introduced along the floor of the nasal fossa like the older form of catheter, and when the beak is fixed in the Eustachian tube, suitable solutions can be injected through it, so thoroughly washing out and medicating the lower part of the canal, without the possibility of any of the fluid entering the middle ear or ascending high up in the tube, the fluid being thrown wholly in a lateral direction through the minute perforations.



Sponge-catheter: showing the manner in which solutions are thrown into the Eustachian tube.

In the first class of cases, those accompanied by turgescence and infiltration of the tubal lips with hypersecretion, two drachms of either of the following solutions were injected through the syringe catheter. Dobell's solution of the following formula: ℞.—Acid. carbol. c. p. gr. jss; sodæ borat., sodæ bicarb. āā gr. ij; glycerinæ ♏x; aquæ dest. f℥j.—M. And a saturated solution of boric acid in water and glycerine, ♏xx to f℥j. This form of treatment has been used with especial care in six cases of chronic aural catarrh accompanied by deafness and tinnitus aurium, and in every case with very marked results; the turgescence of the tubal lips subsided, the secretion became less in amount, and the patients volunteered the statement that they felt better; hearing in all cases was improved—two to five feet improvement for voice—and the tinnitus either grew better or slowly faded away entirely. The injections were made twice a week, the nares and pharynx being meanwhile under appropriate treatment. The syringe catheter has been used as an adjunct to older forms of treatment in from twenty to thirty additional cases, of which full notes have not been kept, but in almost every instance better results were obtained than from the use of the older methods alone.

In the second class of cases either the boric acid solution or the following was used: ℞.—Zinci sulph. gr. ij; acid. boric. gr. x; glycerinæ, ♏xx; aquæ dest. q. s. ad. f℥j, twice a week, a single syringeful (f℥j) being injected into the lower end of each tube. Much less marked results were obtained in these cases, but yet far better than has been obtained by any other method previously used by us. The tubal mouth soon became free from sticky mucus, hearing improved slightly, and the distressing tinnitus aurium was reduced to a minimum. The "lop-sided" "stuffed-up" feeling and dull aural pain, of which these patients almost invariably complain, were entirely relieved in the five cases in which this treatment has been regularly tried. The injections were here continued from three to six weeks.

In the third class of patients, those suffering from atrophic catarrh, but little good was achieved by the use of the syringe catheter—and the same may be said of all forms of treatment of the *nasal* lesions in many cases of this disease. The solutions used in these cases were a Listerine (Lambert) solution of the strength of f℥jss to f℥viij of water, and in certain forms of sclerosis Boulton's solution, of which the following is the formula: ℞.—Tinct. iodini comp. ♏xx; ac. carbol. (cryst.), ♏vj; glycerinæ f℥vij; aq. dest. f℥v.—M., and place in water bath of 100° until the solution becomes colorless.

Some relief from tinnitus and slight though appreciable improvement in hearing were, however, obtained in some of these cases by the use of this instrument along with careful treatment of the throat and nares, the results exceeding our expectations.

We have also used this catheter in a number of cases of acute tubal catarrh following coryza, using solutions of cocaine muriate, morphine sulphate, and boric acid of various strengths, with marked benefit; and treatment by the syringe has done much good in the severe tubal inflammation which usually accompanies purulent otorrhœa, various solutions being used. Prof. C. H. Burnett, to whom I am indebted for many suggestions and favors while devising and testing this catheter, has used the instrument to a considerable extent in his private practice, and tells me he has had markedly good results in some cases of chronic catarrh in which it was regularly used.

Considerable care and experience are requisite to use the instrument properly; after carefully fixing the beak in the mouth of the tube, the solution must be injected without forcing the curved portion forcibly against either wall, and the moment the fluid is thrown in the catheter must be withdrawn, or the patient will be choked by the fluid deluging his larynx as soon as the palate is relaxed. Of course, the rules which govern the introduction of the ordinary Eustachian catheter must be observed here, no force whatever being used. In skilful hands we have never seen the application do any harm whatever, or cause any considerable pain.

Without claiming great things for this little instrument, a year's experience with it has demonstrated to us its great value in selected cases, and we think it may serve a good purpose in aural therapeutics.

The instrument is made by Chas. Lentz & Sons, 18 North Eleventh St., Phila.

49 North 17th Street, Philadelphia

STEEL PIN IMPACTED IN LEFT BRONCHUS FOR TWENTY-THREE MONTHS; SPONTANEOUS EXPULSION AFTER TRACHEOTOMY; RECOVERY.

By H. R. WHARTON, M.D.

Ellen McD., aged seven years, was admitted to the Children's Hospital July 3, 1884, with the [illegible] large glass headed mourning pin, which act was immediately followed by a violent paroxysm of coughing and difficult breathing; both of these symptoms had continued and increased in severity up to the time of her admission into the hospital.

When I saw her a short time after her admission, she presented symptoms of dyspnœa of so urgent a character that I immediately performed tracheotomy, which relieved her dyspnœa, but a careful search of the trachea failed to reveal the presence of the foreign body. A tracheal tube was introduced and the case was carefully watched, but she had no further return of her symptoms of dyspnœa during seven weeks' stay in the hospital.

During this time her temperature was considerably elevated and she presented an area of dulness over the apex of the left lung posteriorly.

The tube was removed at the end of three weeks, and at this time the trachea and right and left bronchi were again explored to discover the presence of the foreign body, but without success. After this the wound healed promptly and the patient was discharged from the hospital. The patient was under observation in the out-patient department of the hospital for some time, but presented no further symptoms of respiratory obstruction, although she had at times a cough, and examination of the chest revealed dulness and moist râles over the upper portion of the left lung posteriorly.

In July, 1885, she had a sudden and severe attack of dyspnœa which passed off in a few hours; in this attack she was seen by Dr. Morris J. Lewis, one of the physicians to the hospital, who described her condition as very alarming.

She presented herself at the hospital a few days after this attack, and examination of the chest revealed the same conditions as are mentioned above.

In June, 1886, she had a severe paroxysm of dyspnœa and coughing, and expectorated a steel glass-headed pin one and seven-eighths inches in length, which had remained in her respiratory passages for twenty-three months. After this she had no further trouble, and the cough of which she had complained at times completely disappeared.

Remarks.—Although foreign bodies may remain impacted in the air-passages for a considerable period of time without producing alarming symptoms, and finally be expelled spontaneously, yet it cannot be denied that their presence may give rise to complications which will place the life of the patient in imminent danger, so that it is generally conceded that surgical procedures should be promptly adopted for their removal.

A point of interest in this case was the entire relief of the urgent dyspnœa afforded by the operation of tracheotomy, although the opening into the trachea was far above the site of the impaction of the foreign body, and I have seen the same relief afforded when the operation has been performed in diphtheritic cases, in which the trachea was found obstructed with membrane adherent to the trachea below the tracheal wound; and I think this can only be explained by the theory that in all these cases the dyspnœa is in a measure due to a reflex laryngeal spasm. The sudden and severe attack of dyspnœa occurring about a year after the introduction of the foreign body into the air-passages, was at the time supposed to be due to the change of position of the foreign body, which, in the light of recent developments, was probably the correct explanation, as the foreign body was subsequently expelled during an attack of this kind.

TREATMENT OF THREATENED RUPTURE OF THE UTERUS BY MANIPULATION AND POSTURE.

By E. P. DAVIS, M.D.,

The following case will serve as a type of some of those in which this serious accident is threatened, and the mode of treatment was found conservative and efficient.

A. B., primipara, a well-formed brunette, aged twenty, had entered the first stage of labor. Abdominal palpation demonstrated that the fœtus occupied the right half of the uterus, its back at the mother's right; the feet in the right upper segment of the uterus; the heart sounds heard plainest on the right side below the umbilicus; the head at the symphysis pubis. Upon vaginal examination the frontal suture was found extending obliquely to the left sacro-iliac synchondrosis: the greater fontanelle lay in the centre. The os uteri was permeable for only two fingers. The inspection of the abdomen showed at the upper border of the lower uterine segment and upon the right a well-marked bulging; it was evident that the distention of the uterus at this point was excessive. Meconium was constantly escaping in small quantities; labor pains were regular, but of moderate strength; fœtal heart sounds were regular and strong.

The fœtal position was evidently strong cephalic extension, and it was probable that operative interference would be necessary; the danger most imminent was uterine rupture.

In the non-dilated condition of the os uteri it was determined to endeavor to secure rotation and spontaneous birth by posture and external manipulation. The patient was accordingly placed upon her left side; an attendant was ordered to sit beside her, and, by gentle manual pressure upon the abdominal projection, aid in rotation; the fœtal heart and the maternal temperature were carefully watched; the pressure made was gentle and intermittent. In less than three hours the tumor had become smaller, and vaginal examination showed an improvement in the position of the head. This improvement continued; the labor was tedious, but operative interference was

not necessary; and in about twelve hours from its beginning labor terminated normally, and the puerperal period was without complication.

In cases of this kind which occur where a trained attendant is not obtainable, a method employed by Betz, and described in the *Wiener med. chirurg. Centralblatt* for November 26, 1886, will commend itself. Betz used a sandbag weighing five or six pounds, which afforded continuous pressure from a broad and perfectly applied surface. This was laid upon the projection formed by the head, and its position changed from time to time as the sensations of the patient indicated. In five hours the natural forces effected rotation, and the labor ended spontaneously.

These simple methods of aiding flexion and rotation at a period of labor when operative interference is difficult and dangerous are certainly worthy of consideration, especially when so serious a complication as uterine rupture is threatened.

MEDICAL PROGRESS.

Effect of Freezing on the Typhoid Germ.—Dr. John S. Billings, U. S. A., writes as follows to the *Sanitary Engineer* of Jan. 29, 1887:

It is well known that freezing water does not destroy the vitality of all living organisms contained in it, although it does appear to kill some of them. To settle the question as to the effect of freezing on the bacillus of typhoid, I have had the following experiments made:

Jan. 10, 1887. Five cubic centimetres of sterilized water in a test-tube were inoculated with typhoid bacillus and exposed to the outer air during the following night at a temperature of about 10° F. It was found solidly frozen in the morning.

Jan. 11, 2 P.M. This frozen mass was thawed, and from it there were inoculated one agar and three gelatine tubes.

Jan. 13, 10 A.M. There is decided typical development of the typhoid bacillus in the agar tube and in two of the gelatine tubes.

Evidently, therefore, the vitality of the typhoid bacillus is not destroyed by freezing.

Drumine: A New Local Anesthetic.—An alkaloid has lately been obtained from the plant, Euphorbia Drummondii, N.O. Euphorbiaceæ, by Dr. John Reid, of Port Germein, South Australia, which promises, if report be true, to compete with cocaine, as an agent for producing local anæsthesia. A tincture of the plant is made with rectified spirit, or proof spirit, acidulated with hydrochloric acid, and, after standing a few days, the spirit is distilled off, ammonia added in excess, and the whole filtered. The residue, after the smell of ammonia has disappeared, is dissolved in dilute hydrochloric acid, and filtered through animal charcoal, to destroy the coloring matter which is abundant and inactive. This filtrate is evaporated slowly, and leaves the alkaloid. It gives a colorless solution, with little taste. It is almost insoluble in ether, freely soluble in chloroform and water, and deposits from solution microscopic acicular and stellate crystals. The crystals deposited from the hydrochloric solution filtered through animal charcoal, are circular or boat-shaped. They are colorless, and seem to be less soluble in chloroform. Sheep and cattle are stated to die in great numbers annually, in consequence of having eaten this plant, the poisonous qualities of which vary in proportion to the quantity of milky juice present. Sheep, bullocks, and horses die in from twenty-four hours to seven days after eating it, all of them presenting paralysis of the extremities, some of them hanging the head as if tipsy; the appetite does not appear to be interfered with. It is curious that the animals avoid the weed at first, except under pressure of hunger, but once having partaken of it, they seek for it and eat it with avidity. Injection of a solution of the alkaloid into the nostrils of a cat, produced stupidity and indifference to stimuli, with a placid, stupid expression like that of an animal under the influence of a narcotic. The limbs appeared paretic. A few drops of a four per cent. solution dropped into the eyes of another cat produced insensibility to the extent of allowing the conjunctiva to be touched, and the orbicular muscle no longer contracted with the same vigor. The pupil was not appreciably dilated. Three grains were then injected subcutaneously, but, beyond local anæsthesia, no effect was noted. A larger dose by the mouth promptly produced paralysis of the limbs, and slow, difficult breathing. When dying, strychnine was injected, but failed to produce any muscular contractions. Ten minims of the 4 per cent. solution injected into the hind leg of a cat, seemed to produce paralysis of sensation, but not of motion. No convulsions ever followed its use. In the course of experiments on his own person, Dr. Reid found that the drug produced anæsthesia, with loss of taste when applied to the tongue or nostril; but small doses swallowed were not followed by any perceptible constitutional symptoms. He tried it subcutaneously in a case of confirmed sciatica in an old man, and the essay was followed by complete, and, so far, permanent relief; in sprains, it was very useful in relieving the pain. Dr. Reid recommends the use of the alkaloid in small operations, local irritation, and sprains.—*British Medical Journal*, Jan. 1, 1887.

Formulæ for Lanoline Ointments.—A compound of diachylon ointment and lanoline, useful in eczema, is as follows:

Unguent. plumbi,	
Lanolinæ	10 parts.
Adipis	10 "

In seborrhœa:

Lanolinæ	℥jss.
Olei theobromæ,	
Adipis	āā ℈iv.
Tinct. benzoin.	℈ij.
Ætheris	gtt. ij.

Used as a pomade.

The following is a lanoline cream:

Spermaceti	10 parts.
Ol. olivæ	30 "
Lanolinæ	40 "
Aquæ	50 "

This is also useful in seborrhœa.

Wilkinson has used the following prescription successfully in scabies:

Sulphur. sublimat.,	
Picis liquid.	aā ℥ij.
Lanolinæ,	
Sapo. virid.	ää ℥ss.
Pumicis pulv.	gr. 75.

In the efflorescences of psoriasis, the following pomade is useful:

[illegible]	[illegible]
[illegible]	[illegible]
Adipis	[illegible]

[illegible] cember 25, 1886.

ABSORPTION OF FAT IN ACUTE INTESTINAL CATARRH.—DR. VIAZHLINSKI, who has been working in Professor Ivanovski's laboratory of pathological anatomy in St. Petersburg, has published an interesting paper on the question of the absorption of fat in acute catarrh of the small intestine. The literature, to which he first alludes, comprises more than ninety papers, etc., including those published by Goodsir, Schäfer, and Watney in this country. His own observations were conducted by inducing acute intestinal catarrh in animals by means of irritant drugs, and then feeding them with milk or other fat-containing food, after which the animal was killed and the intestinal villi examined with the help of osmic acid, which he found the most satisfactory agent for making the preparations. The drugs used were colchicin and croton oil. Several animals (cats and dogs) died, so the quantity of colchicin was reduced from one-thirtieth to one-sixtieth or one-hundredth of a grain, which produced choleraic stools. Croton oil was given in repeated doses of five or six drops, producing diarrhœa with exhaustion. When the animal presented, besides diarrhœa, an inflated abdomen, constant borborygmi, and a considerable degree of exhaustion, an acute catarrh of the small intestine was considered to have been established, and the fatty food was administered. The microscopic observations showed that in catarrhal conditions, as well as in health, the fatty particles are absorbed by their inclusion within round or amœboid cells—*i. e.*, leucocytes—the differences in the diseased state being merely a quantitative one. No evidence could be obtained of any part being taken by the epithelial cells in the absorption of fat.—*Lancet*, Jan. 8, 1887.

PARAFFIN IN SURGERY.—It is perhaps not so well known in the profession as it ought to be that paraffin is a most useful material in surgery, in many cases superseding plaster of Paris. It answers admirably for splints, and for jackets for young children suffering from spinal disease. The advantages of it are that it is clean, light, is capable of being moulded while it is soft, and sets rapidly by pouring cold water on it. It must be procured with a melting point of 130°. When ordering it it is necessary to specify the melting point required. The mode of using it is this: The paraffin is melted by placing a tin can containing it in a pot of boiling water. A muslin bandage well sprinkled with iodoform is put on the limb, or other part to which the paraffin dressing is to be applied. Muslin bandages loosely rolled are allowed to soak in the paraffin for a few minutes. If much support is required a piece of cotton-wool is also soaked in the paraffin. This is placed where most stiffness is wanted, and the bandages applied as for plaster-of-Paris dressing. They may, however, be drawn tight as the paraffin shrinks from the limb in cooling. Cold water is then poured on it, and the limb held in position till the paraffin has set. When a bone tends to project, it can be kept in position by the finger till the paraffin has set. The hole left by the finger can then be filled up with some melted paraffin. In cases of compound fracture the paraffin has the great advantage of not being affected by the discharge from the wound.—*Provincial Medical Journal*, Jan. 1, 1887.

CALOMEL IN HEART DISEASES.—STITLER has added to the studies of Jendrássik on the diuretic effects of calomel, and reports his experiences with fourteen cases. The daily dose was from seven to nine grains, and was invariably followed by good results.

In the case of a man, aged sixty-five, suffering from mitral insufficiency and chronic endarteritis, the symptoms of hepatic congestion, general œdema, and dyspnœa were promptly relieved, and a progressive diuresis occurred which began with the passage of 30 ounces of urine daily, and increased until at one time a maximum of 100 ounces was reached. The diarrhœa caused by the calomel was moderated by opium.

Stitler observes that the drug should be given three or four days before the diuretic effect can be expected, and then it is prudent to suppress it when diuresis is fully established.

It is a valuable adjuvant to digitalis in the treatment of cardiac disease.—*Bulletin Général de Thérapeutique*, November 30, 1886.

THE TYPHOID BACILLUS.—MM. WIDAL and CHANTEMESSE have succeeded in carrying researches on the bacillus of typhoid rather further than Gaffky, who described it. The centre clear space is not, they say, characteristic, as Artaud supposed, for it is found in other bacilli, especially those of old cultures; and it is, they believe, the beginning of the death of the microbe. Spores are produced between 37° and 38° C. It does not liquefy gelatine, and is easily cultivated on potato. Gaffky was unable to find the bacillus in the living subject, or to inoculate it. MM. Widal and Chantemesse have found it during life by making a capillary puncture of the spleen, and they have been able to inoculate both mice and guinea-pigs so as to find the bacillus in the abdominal viscera and lungs. In a case where a typhoid patient aborted in the fourth month the bacillus was found in the placenta.—*Lancet*, January 15, 1887.

TROUBLES OF HEARING AMONG RAILWAY EMPLOYÉS.—LICHTENBERG, of Budapest, has examined the hearing of 250 railway employés, and found 92, 36.8 per cent., in the number who had impaired hearing: 32 of the cases were catarrhal affections, 3 were diseases of the labyrinth, and 30 cases were those of the external ear. These results show the prevalence of impairment of hearing among a class whose occupation exposes them to such diseases, and in whom the public are interested as occupying responsible positions.—*Revue Mensuelle de Laryngologie*, January 1, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE $5.00

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 5, 1887.

ANTIFEBRIN.

FROM the reports in our German exchanges we notice that this new remedy has received an extensive trial, and the results so far seem to indicate that another valuable antipyretic has been added to our resources. Antifebrin is a neutral body prepared by heating aniline with acetic acid, and, when purified by successive crystallizations, it forms a white, odorless powder with a sharp but not unpleasant taste. It is insoluble in cold water, but soluble in warm water, or alcoholic fluids.

CAHN and HEPP, who introduced the drug, have been studying its effects in Kussmaul's wards at Strassburg, and in Nos. 1 and 2 of *Berliner klin. Wochenschrift*, 1887, give a full account of their observations based upon its use in sixty cases. It is given in doses of from five to fifteen grains. Eight grains is the usual dose, and it may be administered in warm water, or in a little alcohol and water, or in capsule. In larger doses it is not poisonous, and from sixty to ninety grains have been taken in the day without any ill effects. Fever patients rarely require more than thirty grains a day in divided doses. It is best to give a single dose of eight grains, to be followed, if necessary, by smaller amounts, in order to keep down the temperature. The effect is usually manifest in an hour, and, as a rule, there is a reduction of from three to five degrees in as many hours. Sometimes the fall is more rapid, and within two hours there may be a drop of five or six degrees. Copious sweating is almost invariably associated with its action. Chills have not been observed. The drug is well borne by the stomach, and in no case caused nausea or vomiting. The duration of action is variable, but in the acute fevers, after four or five hours the temperature gradually rises again. The administration of smaller doses may check this tendency. In typhoid cases an improvement in the general condition was often noticed after its use, and the mind became clearer. In other instances the patients expressed themselves as more comfortable; and in no case was there the depression which is sometimes seen after the administration of antipyrin or thallin. The pulse is also reduced in frequency, and the secretion of urine increased. The authors doubt if antifebrin has any specific action in typhoid fever, but in acute rheumatism it seems to act like antipyrin, not only on the fever but also on the inflammation, reducing the swelling and relieving the pain.

We can confirm these observations on the use of antifebrin. We have found that it acts promptly in comparatively small doses, is easy to take, and is free from the unpleasant after-effects of some other antipyretics. It is a cheap drug, costing not half the price of antipyrin, and seems likely to prove a valuable addition to the pharmacopœia.

INTRAPERITONEAL RUPTURE OF THE BLADDER.

THE late Professor Gross, in 1851, suggested the propriety of opening the abdomen and sponging out the extravasated urine and blood in intraperitoneal rupture of the bladder, with the retention of a catheter in the organ; a suggestion which was successfully resorted to, in 1862, by Walter, of Pittsburg, and, subsequently, with fatal results, the bladder itself having been sutured, by Willett, Heath, and McGill. Hofmokl had a recovery after laparotomy and suture, but in his case the description does not indubitably show that the rent involved the peritoneal investment of the viscus.

The almost uniformly fatal issue of this rare accident, with or without surgical intervention, adds additional interest to two recoveries recorded in *The Lancet* for December 11, 1886, by SIR WILLIAM MACCORMAC. In both cases the belly was opened, the laceration closed, and the cavity of the peritoneum washed out with a one per cent. warm boric solution. In one the rent, four inches long, and extending from the superior fundus to the recto-vesical cul-de-sac, was closed with sixteen points of Lembert's suture, made with fine carbolized silk, and additional catgut sutures fortified the line of union where closure seemed to be insufficient between the silk stitches. In the second case the laceration involved two inches of the upper and posterior part of the bladder, and was closed by twelve points of suture, carried, as in the first case, through the serous and muscular tunics. In one a glass drainage tube, carried into the rectovesical cul-de-sac, was allowed to remain for four days, and a soft catheter was retained in the bladder; but these con-

trivances were dispensed with in the second case, as indeed, they may always be, provided peritonitis is absent, and distention of the bladder with boric solution shows that it does not leak.

It need scarcely be said that it is very desirable to intervene at as early a date as possible when the [illegible] have set in, the recognition of the accident is not always easy. Hence, in the earlier period, instead of practising an exploratory laparotomy in doubtful cases, it will be better to resort to the simple expedient recently described by R. F. Weir, in the *Medical Record* for January 22d. In a patient, seen by that surgeon six hours after a crush, the decision of intraperitoneal rupture was difficult to arrive at, but it was satisfactorily solved in the negative by distending the bladder. A rubber catheter having been passed into the viscus, a Petersen's bag was inserted into the rectum and filled with seven and a half ounces of water. The line of suprapubic dulness having next been outlined by a colored pencil, a similar amount of carbolized water was thrown into the bladder, through which the contour of the viscus could be plainly felt above the line of blood extravasation previously felt in the suprapubic region. The water was then allowed to escape, and measured, when it was found to correspond to the quantity thrown in. Hence, the demonstration of absence of laceration of the bladder was perfect. Weir urges that the distention of both the rectum and the bladder, in making this test, should not exceed seven or eight ounces.

MULTIPLE NEURITIS

Dr. Allen Starr has been particularly happy in his choice of a subject for the first course of the Middleton Goldsmith Lectures. Although it is only six years ago since Leyden established the status of multiple neuritis as a distinct disease, a very large number of facts have accumulated, and an attempt is here made to classify these facts, to weigh their importance, to draw logical conclusions from them, and to present these conclusions in a clear and accessible form. The historical sketch with which the lecture opens presents many points of interest, to which, had we space, we would gladly refer, but we must allude to the vivid description of alcoholic paralysis by that great New England physician, James Jackson, in 1822. As Dr. Starr remarks, it is scarcely possible, at the present day, to add to his account of the main features of this important form of multiple neuritis.

The elaborate discussion of the histology of nerves and of the processes involved in their degeneration and regeneration clears the way for a statement of the morbid anatomy of multiple neuritis. There is still much to be done before we possess a satisfactory anatomical picture of all the stages of parenchymatous inflammation in nerves. In many instances it appears identical with the degeneration which follows compression of a nerve, or destruction of the spinal ganglion cells, while in others it seems to be preceded by an acute diffuse neuritis, with swelling and exudation of serum and leucocytes. An important feature is the frequent limitation of these changes to the peripheral termination of the nerve, and in future investigations this should be carefully borne in mind.

The etiology of multiple neuritis is curiously associated with toxic agents of various kinds. Lead, arsenic, and alcohol are responsible for a large proportion of the cases. The acute specific diseases, diphtheria, smallpox, scarlet fever, measles, and typhoid fever, are not infrequently complicated with motor and sensory disturbances, which we now know to be due to lesions of the peripheral nerves. Syphilis is a doubtful cause. The accurate studies which have been made of that remarkable disease, beri-beri, have thrown important light on the etiology of peripheral neuritis, and the observations which indicate that there is a special bacillus associated with the disease are of special interest in connection with the nerve lesions in lepra, which are apparently induced by the development of parasites in the nerve-sheaths.

MYOSITIS OSSIFICANS

The occurrence of the development of bony tumors in the substance of the muscles is sufficiently rare to make it worth while to call attention to a case of this kind reported recently by Sympson, in the *British Medical Journal*. The patient was a boy seven years old, with a distinct family history of rheumatism, although he had never had this disease, and of an injury—a fall upon the right shoulder, followed by a painful swelling over the scapula of the same side, which subsided and was succeeded by a similar swelling over the other scapula. At the time of observation, March 27, 1885, the boy had no motion in the right shoulder-joint and but little in the left. There were elastic nodulated tumors over both scapulæ, and in the position of the long head of the right triceps. The tumors were tender on pressure.

Nearly a year later a saddle of bone covered the loins, and there was a series of lumps, apparently bony, on the margin of each latissimus dorsi, each teres major, the long head of the right triceps, in the left trapezius below the occiput, in the middle of the right trapezius, and in the supraspinous fossa. The boy also had a curious malformation of the head of each first metatarsal bone, which was large and prominent, while each great toe was small, consist-

ing, apparently, of but one phalanx, and directed toward the fibular side of the foot.

The nature of myositis ossificans is not well understood, hereditary predisposition being the most satisfactory explanation of its cause. The subject has been quite fully discussed by Seidel, in Gerhardt's *Kinderkrankheiten*, Bd. v. Abth. 2; by Pinter, in his *Inaugural Dissertation*, Wurzburg, 1883; by Mays, in Virchow's *Archiv*, Bd. lxxiv., 1878; and by Rogers, in *The American Journal of the Medical Sciences*, vol. xiii., 1833. All of these papers are referred to by Mr. Sympson, who cites other writers on the same subject, but leaves the subject about as obscure as he finds it. The most unfortunate aspect of the whole discussion is the fact that so far no satisfactory method of treating this curious disease has been discovered.

ASPIRATION OF THE STOMACH.

In the *Dublin Journal of Medical Science* for January, 1887, Foy reports a case of alcoholic coma in which he drew off from the stomach, with an aspirator, a quantity of claret-colored liquid. The man had taken claret and whiskey very freely, and for two hours every effort had been made in vain to arouse him. When seen, he was totally devoid of sensibility, the extremities were cold, the face livid, the pupils widely dilated, respiration hardly detectable, no pulse, and the heart-impulse scarcely to be felt. He was bled to sixteen ounces, and while the blood was flowing a fine trocar was thrust through the abdominal wall, upward, backward, and outward from its point of entrance at the sternal end of the eighth rib, and the contents of the stomach aspirated. The quantity of ingesta removed was not stated, but the organ was not emptied, lest the canula should slip and fluid escape from it into the peritoneum. The heart commenced to beat, and respiration was restored. The stomach was then washed out, and soon afterward the man was able to speak, and the next day was well enough to go home.

The operation is defended on the grounds that the respirations were too feeble to permit of the introduction of the stomach-tube, and that apomorphia would not act in a condition of alcoholic coma.

As stated by Dieulafoy, aspiration of the stomach was performed by Paul in 1873, in a case of opium-poisoning in a child. It has also been used in cases of extreme dilatation of the stomach from stricture of the pylorus. In the case here noted we are inclined to attribute the man's recovery to the bleeding rather than to the aspiration, and it is possible that by waiting for the effects of the bleeding, the stomach-tube might have been passed without danger, and the risk of an abdominal puncture avoided.

A new laboratory for the furtherance of medical investigation, which will be built in Brooklyn next spring, promises to be a model institution of its kind. Exteriorly the building will present an imposing appearance, while within the arrangements will have the advantage of a careful study of those of the Johns Hopkins University and elsewhere. Being the outgrowth of private munificence, this institution will be welcomed as another indication that medicine in this country has passed into the era when it will, more often than formerly, share in the endowment gifts of the public-spirited and wealthy.

The new institution will be known as the Hoagland Laboratory, named after its founder, Dr. C. N. Hoagland, of the above city, a physician by education, not in practice, but who has at heart the advancement of scientific medicine. The plan includes a lecture-hall, rooms that will accommodate medical gatherings, and the foundation of a library; and the situation will, doubtless, become the rallying point of a variety of professional interests.

For a quarter of a century Virchow has occupied a prominent place in German politics and, as an ardent supporter of liberal principles and of constitutional government, he has naturally been in constant opposition to Bismarck. Though not an orator, he is a concise and forcible speaker, and his opinions always command the attention of the House. He has endeared himself to the electors of Berlin by an extraordinary devotion to their interests, and in the City Council he has been for years the moving spirit in various schemes of municipal reform. In the election at present going on, consequent upon dissolution of the Reichstag by Bismarck, one contest will be watched with peculiar interest, Von Moltke against Virchow, absolutism against liberalism—the victorious leader of the greatest of modern armies against one of the most remarkable philosophers which this century has produced. Let us hope that our great teacher will be successful.

A contagious disease hospital is greatly needed in Brooklyn. A bill has been prepared for the State Legislature, which is designed to authorize the construction, within the city, of a hospital building that will be equal to the demands of the time in that direction. The present smallpox hospital is an antiquated structure, unsuitable for any but the pauper class, even if suitable for that. It is beyond the city, in the town of Flatbush. It is under the control of the Charities' administration, not that of the health office. Its record as to the mortality of its inmates at times runs unduly high. This condition of affairs has been pointed out, year after year, by the health authorities, and is about the sole remaining deficiency in the hospital service of the commu-

nity, but the necessary endowment by the Act of the Legislature has never been secured, although repeatedly applied for.

In a large city there is always a large number of persons, living in hotels and boarding-houses, domestics and others, who, when sick of a contagious malady, should have isolation and hospital treatment; many of them are able and willing to pay for accommodations like that to which they have been accustomed.

The *Journal d'Accouchements* of January 15th, contains the statistics of the Maternity at Liege for the year 1886. It appears that during the year there were 417 women delivered, not one of whom died, and there were only three who suffered from septic infection, the type in all three being mild. Yet there were several operations done, for example, sixteen applications of the forceps, five internal podalic versions, and in nine women premature labor was induced; there were five cases of placenta prævia, and there were seven women with albuminuria, one of whom had eclampsia. Nevertheless, in 87 per cent. the puerperium was in all respects normal.

Such remarkably favorable results the director, Dr. Charles, attributes to the faithful use of corrosive sublimate, which he prefers to any other antiseptic. That in only 13 per cent. of 417 women delivered in a maternity there should be a temperature of more than 100⅗°, is certainly extraordinary, and seems at once a strong vindication of antiseptic obstetrics, and an example for other maternities, in which like results may be obtained by the faithful use of like means. The use of corrosive sublimate was begun in the Liege Maternity in May, 1884, and up to January, 1887, there have been 987 women delivered without a single death from septicæmia.

The late Dr. Dudley, of Brooklyn, left a bequest of $500 to the Faculty of the Long Island College Hospital, to be used in encouraging their students to diligence in special study. The interest of this sum will each year be given to the senior year student who shall present the best thesis based upon some case that has been clinically observed during the year.

SOCIETY PROCEEDINGS.

[illegible]

The President, Charles McBurney, M.D., in the Chair.

Dr. [illegible] read a carefully [illegible] ing paper on

THE TREATMENT OF FRACTURES OF THE [illegible]

The lack of certainty in the results of treatment in cases of fracture of the patella, and the different values that are put by writers on the subject upon the various methods of securing the fulfilment of the general indications in the management of this injury, with a desire to learn what experience has taught the members of this Society in the matter, are the reasons for submitting to the Society this evening for discussion a short paper on the treatment of fracture of the patella, in order that the conclusions drawn from cases that have been under my care may be either confirmed or corrected.

That the discussion may be as practical as possible, and, at the same time, confined within reasonable limits, I submit the question, What is the best treatment in recent cases of simple transverse fracture of the patella? An answer to this question would, doubtless, be, in the main, the same by each of us; yet we would differ as to the relative importance of the obstacles to be overcome, and the methods available for the purpose.

It is important to remember, in the first place, that the patella lies loosely in the tendon, when the limb is lying in a horizontal position with the muscle relaxed; that the bone can be moved by passive motion freely and easily in a lateral and a downward direction; and, not only so, but can be moved upward, as well, a distance of at least a third of an inch, showing that the ligamentum patellæ is not on the stretch normally; and so free is this motion of the bone, that the leg can be flexed on the thigh to an angle posteriorly of about 130 degrees before the patella becomes fixed and invulnerable. And I have never been able to satisfy myself that this motion was any freer in my own limb, with the body and thigh approximated as they necessarily are in the sitting position, than in the limb of another person, lying on a bed in a horizontal position, although theoretically it ought to be so. The quadriceps muscle also has insertion in the capsular ligament, as well as into the tubercle of the tibia, through the ligamentum patellæ. A considerable part of the vasti muscles converge, it is true, to be inserted into the patella; but there is, after all, a certain part of the tendinous tissue directly continuous with the thin, but strong, capsular ligament. A very little dissection will demonstrate this to the eye; and the power to render tense the ligament is shown by traction on the vasti muscles, in the dead subject; and a still better evidence of the force exerted by the vasti muscles in extension of the leg, in the living subject, is manifested by placing a finger on each side of the ligamentum patellæ, and making the effort necessary in extending the leg, when the ligament will be found not only to become tense, but will perceptibly broaden under this effort. This free motion of the patella is as marked, however, when the limb is horizontal as when it is elevated with the idea of approximating the origin and insertion of the muscle. It seems to me that these points are of value in deciding on what measures we shall use in diminishing the amount of separation that exists when the bone is fractured.

The production of a few cases of fracture of the patella in the dead subject, has thrown some light on the conditions essential for separation to take place in the fragments. I have been struck, in the first place, by the difficulty of producing a fracture of this bone by direct violence even with the leg flexed; and when the bone is sawn partly through from within outward, it is still difficult by any force applied on its external surface, to complete the solution of continuity. When the par-

tial section is made in the opposite direction, from without inward, a slighter force will complete it. When the bone alone is fractured, without any injury to the ligamentous and aponeurotic tissues adjacent, the amount of separation of the fragments is practically nothing; the moderately thin handle of an ordinary scalpel in a post-mortem case can, with difficulty, be inserted flatwise between the fragments. This amount of separation, as we all know, can be increased by cutting the soft tissues at the side of the bone; but even when the capsule was cut to the extent of three inches, laterally, on each side from the edge of the patella, the fragments could not be separated more than three inches and a half, and this required some pressure to be made on the lower fragment; additional separation could be obtained only by further lateral cuts and by vertical incisions upward.

The few attempts that I have made to produce separation of the fragments of fractured patellæ, by injections into the joint, have been almost entirely failures, whether employing air or fluids; for, in order to allow of the separation taking place at all, the aponeurotic tissues of the joint must necessarily be cut more or less, and, although the nozzle of the syringe can be tied in securely, the air or fluid injected, with even slight pressure, finds its way into the areolar tissue outside of the joint cavity, and distends its meshes very rapidly. It seemed to me, however, that there was a slight separation produced by the fluids that remained in the joint, but of this I cannot be sure. Of course, when the bone is broken in the living subject and inflammatory changes obliterate, in part at least, the areolar spaces in the immediate neighborhood of the lacerated capsule, and the fluid accumulates slowly, the problem is somewhat different, and under these circumstances the fluid might act in a way that it would be impossible for it to do in the dead body. I have an impression also, but nothing more, that when the limb was elevated the upper fragment sank a little downward by the weight of the water that remained in the upper part of the synovial sac; I should be unwilling, therefore, to draw any conclusions from my attempts to separate the fragments of broken patellæ by intra-articular injections.

I desire also, in connection with this subject, to describe the post-mortem appearance in two cases of fractured patella, in the Brooklyn Hospital, where death resulted from other causes but within a few days after the production of the fracture. These appearances are, of course, familiar to all of us, but an ocular demonstration of them adds interest to the matter under discussion, and these are the only opportunities that I have had to examine such cases. I can save time and space by speaking of them together.

They were middle-aged men; the fracture was in the right patella; recent in each (within three or four days of death); one known to have been produced by muscular action, and the other probably so, for the patient was intoxicated at the time of injury, and knew nothing of the method of production, but there were no marks of bruising in the soft parts over the joint, except a discoloration near the biceps tendon, the skin was somewhat less movable over the fractured, than over the sound patella; there was a separation of the fragments, of about one and a half inches; the circumference of the knee was one inch in the first, and one inch and a quarter in the second case greater than in the other knee; the lower fragment sagged down to a very slight extent; the fracture was a little below the middle of the bone, and transverse, and the edges felt sharp and were clearly defined.

On cutting into the joint a small subcutaneous clot was found in the first case, and a clot as large and as thick as the palm of the hand, in the second case, over the biceps tendon; the areolar tissue over the fragment was stained with blood, and to some extent matted to the tendinous covering of the upper fragment; the joint had been directly opened by a lacerated wound on each side of the patella in each case about two or two and a half inches in length, and in addition, in the second case, there was a vertical rent, partly through the vastus externus and through the synovial membrane, about three inches in length; there was a moderate amount of bloody serum in each joint, and, in the second case, a few small clots; the upper fragment in the second case was more movable upward than in the first case. Much to my surprise, the fractured edges were not sharp and clean-cut as I had supposed from my examination before the joint was opened, but the rent in the periosteum in front was at a lower level than in the bone itself and quite irregularly lacerated, so that it dropped down like an apron in front of the free edge of the upper fragment, partially covering the broken surface. This was true of both cases, and in the first case there were a few particles of bone adherent to the under side of this periosteal flap. The edges of the fracture were covered and concealed by a firm clot that required considerable pressure with the thumb-nail to remove it, and this, with the periosteal flap already spoken of, was undoubtedly the explanation of my inability to obtain crepitus, although the fragments could be brought into contact with each other. I take this peculiarity in the fracture to be unusual, not finding it described; but it is none the less singular that it should have been found in the only cases that I have had an opportunity to examine after death.

To consider briefly the condition that obtains in the living subject, we may start with the statement that the amount of separation of the fragments depends on the amount of laceration of the ligamentous and tendinous tissues in the neighborhood of the patella, not that in every case of extensive laceration there must necessarily be a wide gap, but that in every case of wide separation there must be extensive laceration as an essential condition. The presence of a considerable separation on superficial examination is proof of a considerable laceration, and we can satisfy ourselves of the presence or absence of laceration in cases where the fragments are close together by gentle flexion of the leg in the thigh, when the quadriceps will be excited to contract, and tend to draw up the upper fragment, while the lower fragment will be displaced downward in cases where there is any laceration. If there is little or no separation under these circumstances, we may know that there is little or no laceration. I have occasionally, with the same object in view, made gentle pressure upward and downward on the fragments, but it has been accompanied by rather more pain than by flexion.

If we now come to consider the causes of separation of the fragments, while we admit that the clot interferes temporarily with the close approximation of the frag-

ments, and the periosteal flap may, in some cases, prove a permanent obstacle to bony union, we must recognize that the real causes of separation are either muscular action or fluid accumulation into the joint, and it seems to me that facts do not warrant us in excluding either one of these causes. It does not seem to me that there is any natural tendency for the muscle to draw the upper fragment upward, inasmuch as the bone is so movable in its tendon; but when fracture takes place, the quadriceps is not excepted in the contraction that takes place in all voluntary muscles after fracture, produced probably either by direct or reflex irritation, contraction that, unless overcome by proper methods, causes a very considerable amount of permanent shortening. There are also frequent contractions of the muscle whenever the patient attempts to sit up, or even to turn, or to raise the hip, etc., for while the muscle is comparatively inactive after fracture, I do not think that it is paralyzed, for with slight stimulus the upper fragment is perceptibly drawn upward by it. Free from any tendency, therefore, to draw the unbroken bone upward, it seems to me when fractures have taken place, that spasmodic action and the usual contraction that occurs after any fracture are causes at work in the production of the gap in fractured patella. And these two kinds of action take place quite as readily with an elevated as with a horizontal limb. It is true, also, that in the few cases of separation of the ligamentum patellæ that I have seen, the bone has been drawn upward, producing a perceptible depression at the point of rupture, even though the joint was not injured, and the amount of fluid in the synovial sac did not seem adequate to account for the displacement.

That the fluid in the joint, however, is a potent element in the production of separation is to my mind quite clear. I saw it very forcibly illustrated in a case of fracture in the Brooklyn Hospital, while interne in that institution. An officer, in helping to transfer an injured patient from a carriage to the hospital entrance, slipped and fell, producing a fracture of the patella. I saw him within five minutes of the receipt of the injury, and found no separation. The fluid accumulated in the joint, and the separation increased as the fluid increased. One would expect that if there were tension of the muscle present, the separation would have taken place immediately; and it might be said that the usual behavior of muscles after fracture would account for the gap as well as the fluid in the joint; but as the fluid was absorbed, the gap diminished, as is not infrequent, and this, I think, could never have been due only to the diminished pressure on the fragments by the fluid in the joint.

Important, therefore, as the fluid in the sac is as a cause of separation of the fragments in the fractured patella, it seems to me a less potent cause than the unusual action of the muscle. For what I saw in a case a few weeks since, is generally true in cases that I have observed: that while the fluid had increased the circumference of the knee by two inches beyond the normal measurement, and aspiration had been suggested, by careful and slow traction on the fragments crepitus could be obtained, although the fragments were quite two inches apart. It must be remembered that the normal capacity of the joint is increased by the rent in the soft tissues, and the opening up to some extent of the areolar spaces in the neighborhood. Of course, it goes without saying, that the inflammatory trouble in the joint enters as a somewhat important element in the treatment of the fracture.

The indications for treatment are plain enough with regard to the coaptation of the fragments; the other indications usually mentioned are the treatment of the inflammation of the joint and its resulting effusion, and the prevention of ankylosis. The first is by all means the most important, and the variety of devices used for the purpose shows, in the main, their inefficiency. It seems to me, in the first place, that elevation of the limb is unnecessary and undesirable for the reasons already given. All those methods for approximating the fragments that make traction on the skin alone, and indirectly only on the bone, are very inefficient in bringing the edges of the fragments together. They have the advantage of early application, of not pressing downward, or tilting the fragments, and thus avoiding the formation of adhesions; but being attached only to the movable skin, they must fulfil very imperfectly this first indication.

Those appliances that are used in which traction is made obliquely backward, and downward, and upward on the fragments, while more powerful and efficient than the former method, have some objections—they cannot be applied until the inflammatory trouble subsides and the fluid is in part at least absorbed, or, if applied earlier, they produce so much pain that the necessary force cannot be used to approximate the fragments, and while pressing on the fragments they at the same time press on the fluid, and in both ways tilt the fragments up; and even when applied late, they press the fragments against the condyles of the femur, and favor the development of adhesions; nor have they a very good control over the upper fragment, for the least involuntary effort at contraction obliterates the depression above the patella, and the bone slides up underneath the dressings. I think the objection made to them by Marinegs has force also, that the constriction of the dressings presses on the nutrient arteries and so interferes with repair.

The most efficient way of approximating the fragments and keeping them in contact, is by traction directly on the bone, and it seems to me that Malgaigne's hooks accomplish this end satisfactorily. They can be applied very early, the traction is made directly on the bone fragments, and is in the long axis of the limb, thus avoiding both tilting and adhesions to the condyles of the femur, the fluid in the joint assisting in lifting the fragments up away from the condyles, the control of the motion in the quadriceps is complete; the fluid does not interfere with their application; they therefore give the best chance for bony or very short ligamentous union. The objections, it seems to me, are not at all sufficient to deter us from using them, in view of the advantages they possess. I have used them in five cases with success, getting, as an immediate result, a shorter bond of union than by any other method, though never union by bone thus far. The pain was not great, the location of the introduction of the points not being specially a sensitive part, and the wound behaving kindly by constant care and cleanliness. The pain of introduction could be diminished by the use of cocaine subcutaneously. The danger of necrosis, of

erysipelas, of suppuration, etc., is undoubtedly to be taken into account, but must be of very rare occurrence.

The objection that, if their use is not followed by bony union, the patient is worse off than if he had a moderately short ligamentous union, on account of the greater liability of fracture seems to me not to be a fair one, for the cases of refracture or rupture under these circumstances have occured soon after the discharge of the patient, while the bond of union was still weak; and we have all seen the same thing take place in cases where the separation was a half inch or more in length, the firmness of the ligamentous band being dependent rather on its age than on its length. The objection that they are "infernal and barbarous" is not sufficiently exact to be answered.

The second indication—the treatment of inflammation and the fluid accumulation—has been fulfilled in may cases by the ordinary rest, evaporating lotions, etc. I never have found it necessary to aspirate the joint, and it must be very seldom necessary to resort to this measure, as the broken fragments can be quite easily approximated with the joint quite distended with fluid; besides, the operation is not entirely free from the dangers of suppuration in the knee-joint.

It seems to me unwise to resort to any active measures in fulfilling the third indication—prevention of ankylosis by flexion even so gentle, before the eighth week at the earliest, and to do this by the third week as is recommended, is dangerous to the integrity of the ligamentous union, if sufficient force is used to affect at all the adhesions.

I should expect, and have obtained the best results in the treatment of single transverse fracture of the patella by applying a posterior splint with the limb horizontal, and lying in a natural position, but not fully extended; by using Malgaigne's hooks, introduced on the first or second day after the receipt of the fracture; by keeping the dressing on for four weeks, then removing the hooks but not the splint, which has been kept on for four weeks more, the patient being in bed; then the patient allowed to be out of bed with the knee immovable for four weeks longer; by the use of the ordinary remedies for the relief of the inflammatory joint symptoms in the early stage, but without resort to aspiration; and by avoiding any effort to disturb adhesions until after the end of the third month, and then only by the patient's ordinary use of the joint in walking, etc.

I have purposely omitted saying anything about unusual forms of fracture of the patella, because they are outside the scope of the present inquiry; and have also said nothing of the treatment of old cases with weak knee by wiring because I have no personal experience to relate.

Dr. Abbe exhibited a specimen and related the case of a young lady who suffered an oblique fracture of the lower third of the patella, the fragments being widely separated. As she was very anxious to have a sound limb, and was willing to take the risk, he exposed the bone, under strict antiseptic precautions, and found a fracture, with two inches separation, the fractured surface of each fragment being covered by a dense layer of torn white fibrous tissue. This, as the normal prepatellar tissue torn like two frills, and so disposed over the bone that osseous union could have been impossible, even if coaptation had been obtained. These fringes were cut away. The patella was wired with silver, the joint irrigated with sublimate, 1 : 5000, and drained laterally. Primary union, without joint disturbance, followed. Three months have elapsed, and the patella is one solid bone. The patient is walking with a cane, and without splints. Fibrous ankylosis exists, which bids fair to yield in the course of time, and seems largely extracapsular, but at present allows flexion of about only ten degrees. The patient is greatly pleased.

He thought there was always some risk of ankylosis following this method, but that with improved technique this would be done away with. One step toward improvement would be in leaving a drainage tube in the joint interior as short a time as possible, and perhaps do away with it altogether. In the worst event he believed a partly ankylosed joint with solid patella, better than a weak unreliable knee with gaping fragments. If a joint suppurated, he believed it was always due to contamination from defective antisepsis.

Dr. Lange said that he had heard, with much interest, the reference to the fibrous tissue that was found covering the ends of the fragments, since he had noticed the same appearance. He had performed the operation of wiring the patella in five cases, and believed that it is safe and reliable, provided the surgeon exercise the proper care. He had so far operated on special indications only. The first patient was a stewardess on board a steamer, who wished particularly to have a reliable limb in order to be able to go up and down the steep ship-stairs, as her living depended on this. The second patient was a lady, who, for many years before, had had an amputation of the thigh on the opposite side. The third one had fractured both patellæ several years before; one was not operated upon. There existed a very wide gap, but the limb was partially useful. On the side of the operation the fracture had been of more recent occurrence, and though the distance between the fragments was considerable, the latter could, with some difficulty, be approximated.

In all of these cases, two of which were operated upon within eight or ten days after the accident, complete recovery took place, and the limbs have become quite useful.

The fourth case was that of a vigorous man, who, after a fracture near the attachment of the ligamentum patellæ, had lost all control over the extension of his leg, and was obliged to depend upon an apparatus. There existed a wide diastasis of the fragments, which could be brought in contact only after the quadriceps tendon had been partially divided at several points, at some distance higher up, between the muscular bellies of the vastus. The capsule was also incised freely. The fragments were forcibly approximated by coarse silk ligatures. This man had a stiff, but useful, limb. It was impossible to say whether the slight motion that was present at first, had improved or not. The shape of the patella and its lower surface had to be smoothed. Probably a comminuted fracture originally occurred.

The fifth case was not equally favorable. A strong man, aged about thirty, fond of athletics, had fractured his patella near the upper margin. There existed extensive extravasation and rupture of the capsule. The operation was done on the third day after the injury,

the patient himself being anxious to secure the best possible result. Borosalicylic solution was used as an antiseptic during the operation. The patient did not behave as quietly as he might after the operation, and made very unwise movements with his limb. Suppuration set in, and the limb became quite stiff, the semilunar cartilages having been detached by necrosis. Probably it would have been wiser to delay the operation until absorption of the extensive extravasation had taken place. In all of the cases, except one, strong silkworm gut was used to suture the fragments.

DR. HALL stated that he had wired the fragments of the patella in two cases of recent fracture. In both instances he had found coagulated blood between the edges, the extravasation in one case being very extensive and having ruptured into one of the prepatellar bursæ, so that the patella could with difficulty be felt. Aspiration was unsuccessful as the blood was coagulated, and fearing much stiffness on account of the hæmarthrosis, suturing was resorted to. Bony union was obtained in both instances. Silver wire of one-sixteenth of an inch was used. The special interest of the cases lay in the fact that there was no interposition of fibrous tissue, the fragments being separated to the extent of half an inch by a firm blood-clot; particular attention was called to this, as the other condition had been described as invariable, and as being the cause of non-union. In a case of old fracture recently seen, only the upper corner of the bone was broken off, with practically no separation, and no interference with the insertion of the quadratus femoris into the larger fragment, so that the patient had perfect use of the leg, although union did not occur.

DR. SANDS asked concerning the amount of motion in the injured limbs.

DR. HALL replied that one of the patients could flex the limb only about fifteen degrees when the dressings were removed, but three or four weeks later, when last seen, had motion almost to a right angle, and was improving daily. No passive motion had been employed. In the other case flexion was limited to about twelve degrees, but the range of motion would undoubtedly be greater in the course of three or four months.

DR. PETERS asked how long the dressings were retained, to which the speaker replied, for six or seven weeks.

DR. LANGE remarked that he had obtained good results with sutures of coarse silkworm gut.

DR. SANDS thought that all surgeons had found the treatment of fractured patella unsatisfactory, it being impossible to maintain perfect apposition of the fragments. Treves had recently recommended anew the use of Malgaigne's hooks, piercing the joint and embedding them firmly in the fragments, due antiseptic precautions being employed. The speaker rather liked this treatment. After all, it is not so important to obtain bony union, as the patients can get on very well without it. However, the best results will doubtless be obtained when surgeons are able to open the joint safely every time, and to wire the fragments. It should be remembered that this is yet a serious operation, which is sometimes followed by suppuration, ankylosis, or even by death. He had found that patients rarely wished to run any risk, when the nature of the operation was frankly related to them. Even when successful the operation often leaves some stiffness of the joint, with diminished flexion, on account of the thickening which attends the healing process. Dr. Sands confessed that he, at present, occupied a decidedly conservative position with regard to the operation and would be unwilling to have it performed upon himself. But he was confident that the dangers now attending it will be finally overcome.

DR. WEIR explained that Mr. Treves's method of introducing the hooks is quite simple. He relied upon the maintenance of perfect cleanliness by means of water.

DR. HALL believed that a Philadelphia surgeon had written a paper some years before in which he reported about fifty cases of fractured patella, in the treatment of which Malgaigne's hooks had been used with good results.

THE PRESIDENT thought that the radical operation should be more carefully studied before it is generally advised, since its remote consequences are not always satisfactory. He had observed a case in which bony union had been obtained by wiring the fragments, but three months after they separated, on the application of slight force; in another instance suppuration occurred, and motion was subsequently limited to fifteen degrees. Another case of suppuration was reported at Bellevue Hospital.

DR. POORE asked if it was not true that the joint is frequently stiff after the operation.

DR. LANGE replied that this depended to a great extent upon the after-treatment. In three of his cases there was perfect mobility, while in the others motion was limited. The condition doubtless improves in time under the influence of massage and passive motion.

CORRESPONDENCE.

CHLOROFORM AND ETHER DEATHS.

An article published by me in THE MEDICAL NEWS for January 8 was intended simply to put upon record a clinical experience, which seemed to me important as demonstrating that a dater attended the administration of an anæsthetic mixture generally regarded as safe. Among the remarks appended to my account of that case was one calling in question the statement made by Dr. J. C. Reeve, that her "in the human subject may cause death as suddenly, as unexpectedly, and in the identical manner that chloroform does." Dr. Reeve, in an article in THE NEWS for January 22, asserts the accuracy of his statement, and adduces a number of instances in support it.

I beg to disclaim any intentional discourtesy to Dr. Reeve in my expression of dissent from his opinion; nor did I mean to throw down a challenge upon the subject. But I feel constrained to defend my own view, that there is a marked difference between ether deaths and chloroform deaths; and shall call Dr. Reeve's own cases in evidence.

Let me first very briefly review these:

In Case I. there was "an extremely softened spleen."

Case II., a woman, "aged fifty-five, in very poor health."

As to Case IV. Dr. Reeve says "the report of the autopsy makes no mention of" blood in the trachea. Certainly not, for the account (in the *Boston Med.*

and Surg. Journal for November, 1875, taken from the *N. Y. Herald*) there is no mention of any autopsy.

In Case V. there were "Bright's disease, chronic pleuritis, and embolism of the pulmonary artery."

Case VI. (Lowe's case). As to this, I must speak a little more fully. Dr. Reeve says of it: "The report I have says 'there were some nodules of cancer in the liver and lungs.'" My own quotation was made from Mr. Lowe's original statement in the *British Medical Journal*—"studded throughout both lungs, but more particularly toward the base, were numerous small, hard, cancerous nodules."

Case VII. was that of a "male, aged sixty-nine, much exhausted; strangulated hernia; heart flabby, left ventricle not contracted, lungs emphysematous, and bronchi filled with purulent mucus."

In Case VIII., that of a man, aged sixty-two, addicted to drink, there were found "pleuritic adhesions, atheromatous aortic valves, congested liver and kidneys, the latter studded with cysts."

Case IX. was that of "a feeble old man of sixty-seven, with strangulated hernia." It seems to me that this was a case of "asphyxia," as stated, by the "copious bronchial secretion" which "kept filling the patient's mouth." Such drowning is sometimes met with in various thoracic affections of old people.

In Case XI., that of a man, aged sixty-two, "the lungs were emphysematous and congested, and there was bronchitis (?). The heart was flaccid and fatty, with adherent pericardium."

In Case XIII., that of a man, aged fifty, "suffering from severe inflammation of the bowels, due to obstruction," there was found at the post-mortem "considerable purulent effusion in the peritoneal cavity; at the lower part of the descending colon was a malignant mass of the size of a small cocoanut, blocking the canal. In the right ventricle of the heart was a fibrinous clot attached to the tricuspid valve."

The other cases are all deficient, as indeed Case IX. was also, in statement of post-mortem appearances. But in Case XII., the only one in which a young person was the victim, it is stated that the girl, aged ten, was "much emaciated, and looking very ill; to be sounded for a calculus."

Now, I would ask to contrast with this series of cases a few only of those of chloroform death which have met my eye in the hasty glance over some medical journals which the pressure of other work has allowed me to take.

I. A stout young man operated on by Dunsmure for stricture of the urethra. With the exception of a few old pleuritic adhesions, every organ presented the most exquisite specimen of health. (*Med. Times and Gazette*, October 15, 1853.)

II. Young woman, chloroformed for an amputation of the great toe. All the organs found perfectly healthy. (*New Orleans Med. and Surg. Journal*, January, 1854.)

III. Richard's case of uterine polypus. Nothing of interest observed at the post-mortem. (*Lancet*, April 29, 1854.)

IV. Man, aged forty; eyeball excised at the Royal Ophthalmic Hospital, London. No cause of death discovered at the autopsy. (*Med. Times and Gazette*, April 14, 1855.)

V. Porter and Brewer's case; trooper, with dislocation of thumb. Nothing detected at the post-mortem except "congestion of the scalp and head." (*Maryland and Virginia Med. Journal*, February, 1861.)

VI. Lane's case; boy, aged eight, to be operated on for the scar of a burn. All the organs found healthy. (*Med. Times and Gazette*, November 16, 1861.)

VII. Healthy looking man, aged thirty-three, with a sloughing sore on the penis to be cauterized. No sign of disease discovered at the autopsy. (*Lancet*, November 19, 1864.)

VIII. My own case. Man, chloroformed for the second time for reamputation of leg. No visceral lesions sufficient to account for death. Heart and lungs perfectly healthy. (*Am. Journal of the Med. Sciences*, January, 1865.)

IX. Woman, who had previously taken chloroform; had to have a tooth drawn. At the autopsy all the organs were found perfectly healthy. (*Med. News and Library*, June, 1866.)

X. Le Fort's case. Man, aged thirty, with anal fissure. Nothing noted at the post-mortem but two small pulmonary cavities. (*Med. News and Library*, June, 1873.)

XI. Brakeman on a railroad, chloroformed for the extraction of a tooth. No disease found. (*Boston Med. and Surg. Journal*, October 1, 1874.)

XII. Gant's case. Boy, aged fourteen, with suspected dislocation of the hip. All the organs sound. (*Brit. Med. Journal*, December 19, 1874.)

XIII. Man, aged fifty-six, operated on for fistula and hemorrhoids. No organic disease discoverable. (*Brit. Med. Journal*, March 17, 1877.)

XIV. A young lady who had had five teeth extracted under chloroform, was recovering, when more chloroform was given, and she died. A post-mortem examination showed all the organs to be healthy. (*Med. News and Library*, March, 1878.)

The above cases are only selected as having distinct statements in regard to the post-mortem appearances; otherwise they are taken at random. By reason of their incompleteness in this respect, I have not noted here such cases as one mentioned by Anderson (*Cincinnati Clinic*, March 31, 1877), in which a strong, healthy country boy, who had taken chloroform a year previously, inhaled it (for some purpose not stated) and was recovering, when a few more whiffs were given him with fatal effect; nor another recorded in the *Association Journal* for May 26, 1854, where a girl of thirteen, of strong constitution, was chloroformed for the removal of a lipoma of the back, fell forward, and died in a few minutes. Nor have I regarded any cases of self-administration. Yet, so far as my knowledge goes, all these cases, like those above adduced by me, are without parallel in the history of anæsthesia by sulphuric ether.

I am not aware that I have ever denied the occurrence of deaths during the administration of ether, or as a result of it; although young men do sometimes make assertions which more mature experience leads them to correct or modify. But with nearly all the cases brought forward by Dr. Reeve I had been familiar, as well as with some others not mentioned by him; notably that of Dr. Dandridge, of Cincinnati, reported in 1880, and that of Dr. Roberts, of Philadelphia, of about the same date. And in every one of these cases, so far as I know them, in which an autopsy was made, there was

discovered serious organic disease, perhaps not in itself lethal, but too grave to be overlooked as contributory to the fatal result. Chloroform needs no such assistance.

Upon the production of one case in which ether has proved fatal to a healthy young person, inhaling it for a slight operation, and in which an autopsy shows no organic disease or lesion, I will at once admit that my objection to Dr. Reeve's statement falls to the ground, and that ether does kill in the identical manner that chloroform does.

In conclusion, I would quote a passage which by the merest accident caught my eye a day or two since. It occurs in a review of Valette's "Clinique Chirurgicale de l'Hôtel-Dieu de Lyon," in the *British and Foreign Medico-Chirurgical Review* for January, 1876:

"One lecture is devoted to a comparison of the relative safety of ether and chloroform, and M. Valette pronounces unhesitatingly in favor of the former. He does not deny that deaths occasionally occur under the influence of ether; but in the cases he has been able to collect, there is a remarkable difference between these and the similar accidents from chloroform. A large number of the fatal cases under chloroform have occurred when the anæsthetic was being administered to a patient apparently in good health, and suffering from some trivial local malady. On the other hand, those occurring under ether have always been in cases of the gravest character, and in which the patient was either exhausted by previous disease, or suffering from the shock of some severe injury. Again, he points out that death, when resulting from the effects of ether, has always been preceded by warning symptoms; whereas with chloroform it has often been sudden, and utterly without warning of any kind."

NEWS ITEMS.

DISEASE AMONG THE INDIANS.—DR. WASHINGTON MATTHEWS, surgeon in the United States Army, has made a valuable contribution on the causes which are at work in carrying off the Indians of our country. One of the most important of these he finds to be consumption. From the census of 1880 we learn that, while the death-rate among Europeans is 17.74 per thousand, and that among Africans 17.28, the rate among the Indians is no less than 23.6. In diarrhœal diseases the Indian death-rate is not greatly in excess of that of the other classes. Measles gives a mortality of 61.78 per thousand. But it is under the head of consumption that the difference between the Indians and the blacks is most conspicuous; the rate among the former being 286 as compared with 186 among the latter, while among the whites it is but 166 in the thousand. Dr. Matthews finds that, where the Indians have been longest under civilizing influences, the consumption rate is the highest; meaning by the term "consumption-rate" the number of deaths from consumption in a thousand deaths from all known causes. Thus the rate among reservation Indians in Nevada is 45; in Dakota, 200; in Michigan, 333; and in New York, 625.

A PASTEUR LABORATORY AT NAPLES.—The Sanitary Commission at Naples has determined, upon the recommendation of Semmola, to erect a laboratory for the practice of Pasteur's method of inoculation. The circular which announces its erection, urges the need of further experimentation with this method, to enable an accurate estimate to be made of its worth.

INSANE DEPARTMENT OF THE PHILADELPHIA HOSPITAL.—Dr. A. J. Smith has been elected first assistant in the insane department of the Philadelphia Hospital, to succeed Dr. J. C. DaCosta, who has been called to a similar position in the Pennsylvania Hospital for the Insane.

FEMALE MEDICAL STUDENTS IN FRANCE.—The medical faculty of France has this year 108 female students —namely, 83 Russian, 11 English, 7 French, 3 American, 2 Austrian, 1 Turk, and 1 Roumanian.

DEATH FROM CHLOROFORM.—The death of a man, aged fifty-four, while under the influence of chloroform, administered for the purpose of performing an operation on a long-standing disease, recently occurred at Bradford, England. The evidence given at the inquest showed that every precaution was taken, and that an examination of the heart before the administration revealed no evidence of disease. An ounce of brandy was administered three-quarters of an hour before the administration of the chloroform. Immediately on the completion of the operation the heart's action was found to have ceased. It was stated that the deceased had successfully undergone a similar operation twenty-five years before.—*British Medical Journal*, Jan. 15, 1887.

TOOTH POWDERS.—According to *The Lancet* precipitated chalk forms the best basis for a tooth powder, to the base of which may be added pulv. saponis and ol. eucalypt. a drachm of each; and, if there is no objection to the taste, half a drachm of carbolic acid.

LECTURE II.

January 28, 1887.

MULTIPLE NEURITIS, AND ITS RELATION TO CERTAIN PERIPHERAL NEUROSES.

IN the last lecture we studied the history of multiple neuritis, and incidentally obtained some clinical pictures of various forms of this disease. We also discussed its pathology and its etiology. This evening we must look more carefully at the symptoms presenting themselves in the different varieties of the affection.

An etiological classification of the cases of multiple neuritis appears to be the one most useful to the clinical observer; and as the forms vary considerably in their symptoms, we shall perhaps arrive at a more definite knowledge of the disease if we consider each of the classes separately. It is possible to distinguish—

1. Toxic cases, due to poisoning by alcohol, arsenic, lead, and bisulphide of carbon.

2. Infectious cases, due to the direct action upon the nervous system of the infectious agents producing diphtheria, variola, typhoid and typhus fevers, severe malarial fever, and tuberculosis; to which must be added the agent causing the epidemic form of neuritis known as kakke or beri-beri.

3. Spontaneous cases, due to uncertain causes, among which cold, and exposure to damp and wet, and to overexertion, may find a place.

1. *Toxic Cases.*—(*a*) *Multiple neuritis, due to poisoning by alcohol.* While alcoholic paralysis has been universally recognized for many years, it is only within a short time that the symptoms and pathology have been brought into a logical connection. It is to Moeli,[1] of Berlin, and Dreschfeld,[2] of Manchester, England, that we owe the most important recent contributions to the knowledge of this form of neuritis, though the work of Henry Hun,[3] of Albany, and of Bernhardt,[4] of Berlin, cannot be passed over without recognition.

It will be remembered that among the first cases of multiple neuritis in which an autopsy was made, viz., those of Lancereaux,[5] the disease was traced to alcoholism. Lancereaux deserves the credit of demonstrating the pathological basis of alcoholic paralysis, for the descriptions of its symptoms previously given by Jackson and Hun were not accompanied by post-mortem records. But Lancereaux's observations were for many years overlooked by physicians outside of France; and in England, where the disease is well known, it was ascribed, as lately as 1883, to a spinal lesion.[1] But in 1884 Dreschfeld combated this theory, and called attention to its true pathology, showing that cases formerly supposed to be spinal paralysis were really due to an affection of the peripheral nerves.

All observers have emphasized the fact already noted by Jackson, that the disease is especially frequent among females. Males are not, of course, exempt from alcoholic paralysis, but in them the poison seems more liable to manifest itself by acute cerebral symptoms than by those of disease of the peripheral nerves. It is especially frequent among those persons in the higher classes whose nervous organism is highly developed, and who lead a comparatively inactive life. It seems not at all improbable that sedentary habits predispose an alcoholic drinker to this disease, and hence active workers, male or female, though taking an equally large amount of liquor as the luxurious drinker, escape. All alcoholic drinks are not equally prone to produce paralysis. It is the spirituous liquors—brandy, whiskey, gin, and rum, and the liqueurs, absinthe, vermouthe, etc.—which are dangerous. And it is only after these drinks have been consumed in large amounts and for a considerable length of time that neuritis develops. Its onset, though often apparently very sudden, is usually gradual. For months the patient has suffered from chronic gastritis, insomnia, general neuralgic pains, or severe pains in the joints or limbs, and from tremor and a certain feebleness in movement, when all at once her legs give way beneath her, and after the sudden fall she finds herself unable to rise. Thus a patient of mine, after a year of such premonitory symptoms, was seized with paralysis quite unexpectedly when getting out of bed in the night. This paralysis soon becomes complete in the feet and legs below the knees, and may advance up the thigh. It next attacks the hands and forearms, and while in all extremities it is often greater in the extensors than in the flexors, in some cases both groups of muscles become entirely helpless. This has been the case in three patients under my care. The paralyzed muscles are flabby, and soon become atrophied, they have no excitability to mechanical irritation, and the tendon reflexes are lost. They fail to react to a faradic current in the majority of cases, though occasionally a very strong current may produce a response. When galvanism is applied the reaction of degeneration is found to be present. No stimulus can be given to the muscle by sending a current through its nerve, and the positive pole produces more marked contractions with an equal current than the negative

pole when placed on the muscle, and then it is only a slow or vermiform movement, not the quick jerk of health. It is also found that strong galvanic currents have to be used to produce any contraction at all. The paralysis of the muscles may advance rapidly in severe cases, involving the motor cranial nerves, the muscles of the trunk, and, lastly, the diaphragm, thus causing death. More frequently, however, it is arrested when only the distal parts of the extremities are involved, and then it gradually subsides until recovery is complete. The position assumed by the paralyzed limbs has been thought to be almost characteristic. There is dropped wrist quite similar to that seen in lead-palsy, and also dropped foot, due to the falling forward of the foot from its own weight, since the anterior tibial muscles are weak. This deformity is increased by the fact that the patients lie in a recumbent posture with the feet extended, and when the flexors of the toes are but slightly affected, as sometimes is the case, their unopposed contraction serves to exaggerate the malposition. If there is entire paraplegia the legs and thighs may both be extremely flexed, so that the heels touch the buttocks, but this is exceptional. While the dropped wrist is the usual deformity of the hands, cases are recorded in which the paralysis was limited to single muscles and to muscles supplied by single nerves. Thus, Lilienfeld describes a weakness of the extensors of the thumb, fourth and fifth fingers, and Leudet mentions a paralysis of the ulnar nerve. In one case of my own the main *en griffe* was the deformity noticed, indicating a weakness of the interossei only. Such cases as those of Hun,[1] where a facial paralysis was seen, or of Lilienfeld,[2] where double abducens paralysis occurred, are certainly rare, and still more so are those in which irregular rapid pulse has been ascribed to an affection of the pneumogastric.

To the physician these motor symptoms, and the œdema, occasional lividity, profuse sweating, and glossy skin, so often associated with them, are very noticeable. But the patient suffers far more from the disturbance of sensation. In the description of Jackson, the pains were graphically portrayed. They are the cause of terrible agony, sufficient to produce insomnia, and wearing seriously upon the endurance of the sufferer.

In addition to pain, hyperæsthesia is not infrequently observed. It is usually quite extensive in the legs, though in cases of poisoning by absinthe it has been limited to the soles of the feet. The muscles, as well as the skin, are sensitive to handling and to pressure, and marked tenderness in the course of the nerves is always elicited by examination. In one of my cases soon after the onset, the patient could not bear to be touched or moved, though perfectly unable to help herself. Charcot goes so far as to say that muscular sensitiveness associated with flaccid paralysis is pathognomonic of alcoholism.

Paræsthesiæ are always complained of. Numbness, tingling, and formication are frequent. In one of my patients the sensation was as if heavy bracelets were around the wrists, and as if very tight drawers were on the legs. At other times she felt as if the limbs were swollen, and as if the skin was about to burst. Such sensations may cease as the case increases in severity, and give place to a total lack of sensation in the parts. They return, however, with advancing recovery, and are among the last symptoms to disappear.

Abolition of tactile sense, and to some degree of muscular sense, is the rule after the paralysis is developed. Temperature-sense and the perception of pain are never wholly lost, but may be delayed in transmission. The anæsthesia may be limited to irregular areas, and may be only in the cutaneous distribution of one nerve, but is usually found over the entire distal part of the paralyzed limb. Usually the cutaneous reflexes are preserved. The loss of muscular sense is, in some cases, so marked a symptom, and one of such early occurrence, that Dreschfeld distinguishes a class of cases which he terms ataxic rather than paralytic. And this distinction is perfectly justifiable, for in many cases it is the incoördination which attracts the attention of both the patient and the physician. It is this class of alcoholic cases which may be mistaken for locomotor ataxia, and which have been named by French writers pseudo-tabes alcoolique.[1] But ataxia is not exclusively limited to this class of cases. It may be present in some degree in cases of paralysis, and during recovery from paralysis the deficiency in coördinating power may become evident, and appear to retard the progress of the case. Nor are the cases of ataxia, on the other hand, free from paralysis.

And this fact is proven by the observations of Westphal[2] and Charcot. For by contrasting the walk of a true ataxic patient with that of an ataxic alcoholic patient they have each discovered several points of difference. The ataxic patient throws the foot forward with undue violence, the toe lifted high in air, and brings first the heel down forcibly and then the entire foot. The alcoholic, however, has some weakness in the muscles of extension and cannot raise the toe. He, therefore, lifts the foot high in order to step over the hanging toe and not to trip on it, but the motion is made without undue force. He then throws the foot forward in order to throw the toes up and get them out of the way as he brings the foot down to the floor. The motion is awkward and has an appearance of one stepping over high obstacles, but it is a voluntary attempt to remedy a deficient power—not the involuntary awkwardness of a man unable to manage strong muscles. There may be in both patients some tottering, and swaying when standing with the eyes closed, the so-called Romberg symptom, is common to both locomotor ataxia and alcoholic neuritis. Dejerine describes the following cases, in which the symptoms resembled that of tabes.

Observation VIII.—Male, aged forty-two, a hard drinker, complained for four months of shooting pains in the legs, and noticed a gradually increasing difficulty in walking, which was worse in the dark. He also had found his feet swollen at times, and had some difficulty

[2] Westphal: Ueber eine bei chronischen Alcoholisten beo[illegible] Amsden, 1876. Charcot: Leçons du Progrès Medical, 1878.

in micturition. Examination on admission to the hospital showed a high grade of ataxia in walking, Romberg's symptom, loss of tendon reflexes, anæsthesia almost total of entire body, considerable analgesia with retardation of sensations of pain, temperature sense being preserved, and loss of muscular sense in the legs. The muscles were slightly feeble and a little diminished in size. It could hardly be said that there was paralysis or atrophy. The diagnosis made was locomotor ataxia of an unusual type. The onset was so rapid, the anæsthesia so extensive and severe, the paresis of the limbs, though slight, so evident, that it differed from a typical tabes. But no other diagnosis could be made from the symptoms. The patient died of chronic nephritis six weeks after admission. The autopsy showed the spinal cord to be normal. But in the cutaneous and to a less degree in the intramuscular branches of the nerve, as well as in the distal parts of the nerve trunks, a high grade of parenchymatous neuritis was found. The nerve tubes had lost their double contour, the myelin sheath was segmented, the protoplasm was increased, the nuclei multiplied. The nerve-trunks on the plexuses, and the nerve-roots were normal. The nerves of the legs were more deeply involved than those of the arms.[1]

The second case, in a female forty-nine years of age, presented almost identical symptoms and lesions.

The special senses are occasionally affected in cases of alcoholic paralysis. Amblyopia has been observed, and also defective vision from central scotoma. The field of color-vision is often contracted even when sight is preserved. There may develop a true optic neuritis, evident to the ophthalmoscope, and this may go on to optic nerve atrophy.[2] Inequality of the pupils is frequently seen, as is also a moderate contraction of the pupil. All these eye symptoms, occurring as they may in a case of the ataxic variety, make a differential diagnosis from locomotor ataxia difficult. The Argyle Robertson pupil (which contracts in accommodation but not to light) has not been seen in alcoholic cases, while it is an early symptom of tabes.

One feature of alcoholic paralysis remains to be noticed, viz., the cerebral symptoms. These are hardly ever wanting. There is at first the excitement rising to the degree of active delirium, with illusions and hallucinations of the various senses; there is the insomnia which so soon exhausts the patient if it is not remedied; there is the loss of memory, especially of recent occurrences; and the lack of power of attention or concentration which prevents intelligent conversation. The indifference to bodily wants may be so great as to lead to uncleanliness, and since paralysis of the sphincter is the rare exception, incontinence is usually to be ascribed to the mental state It is useless to attempt to get any reliable history of their illness from these patients. Their statements are unintelligible or unreliable. And here it may be well to notice a symptom first remarked by Strümpell.[3] These patients will relate occurrences as having happened recently with much elaboration of detail, when as a fact the story is entirely a product of their imagination. Thus one patient of my own who had been confined to bed for many days, told me one afternoon that she had been out to see an eminent gynecologist during the morning; had gone to his office and waited for him several hours; had seen other patients there, and finally had been told by the doctor's brother that he would not return in time to see her, so she had come home again. And this was all related in apparent good faith, so that I have no doubt that she believed that what she said had occurred. With the possibility of such delusions in view, it is evident that the statements of these patients cannot be accepted regarding anything, especially as to their own history.

One patient, who was admitted to Bellevue Hospital during my service there, told me a different history of her case every day for a week, and it was only by interviewing her friends that the correct account was obtained.

The course of alcoholic neuritis is quite uniform. After a sudden onset, the symptoms suddenly advance to a high degree, which is reached in a week or two from the beginning of the paralysis or ataxia. Then they may increase further, and cause death by respiratory paralysis. Usually, they remain stationary for a time, and then gradually subside, the entire duration being from two months to a year. Individual muscles regain their power, tone, firmness, and electrical reaction slowly, and during recovery the tingling and numbness in hands and feet may be severe. In a few cases the muscles become contractured, and permanent deformities, only to be overcome by long-continued massage, or by operative measures, develop. When the fact is considered that those who recover rapidly, rarely fail to resort again at once to the use of stimulants, and thus expose themselves to the danger of a relapse, the ultimate fate of the chronic cases is hardly more serious than that of those who get well.

As examples of the paralytic form the following cases are cited:

Observation IX.—A baker, aged forty-seven, phthisical, a moderate drinker, had suffered for several years from numbness of the hands and legs; and for a year before the acute invasion of his illness, from a slight weakness of the legs and uncertainty of motion in walking. This weakness became much worse during the spring of 1881, so that all summer he was confined to his room, though he managed to walk a little. In November, after an uneasy night, during which he was delirious, it was found that he could not move his legs at all, and that his arms were powerless. He was brought to the hospital November 25th, when a total paralysis, with atrophy and loss of tendon reflexes, was discovered in legs and arms, as well as slight disturbances of sensibility in the legs, consisting of a delayed sensation of pain. His mental condition was a weak one, but he answered questions rationally. The face was in no way affected. No involuntary evacuations. Electric examination showed a great diminution, and in many muscles total loss, of faradic excitability when the current was applied both to nerve and to muscle. With the galvanic current few contractions could be elicited by exciting the nerves, and by exciting the muscles the slow contractions characteristic of RD, as well as the predominance of AnCC over KCC, were

[1] Decrine: Arch. de Phys. Normale, 1884. For other [illegible] cases, see Dreschfeld, loc. cit.

[2] Brissaud: Des paralysies toxiques, p. 31. Paris, 1886.

[3] Strümpell, Arch. f. Psych. 1883, xiv. 339.

present.[1] The mechanical excitability of the muscles was not impaired. There were no pains. During the following three months there was little change in the condition, except that his mind was not clear, and that he told extraordinary stories of having been out walking, of having made purchases, etc., when, in fact, he could not move from the bed.

His pulse became more rapid during this time, averaging 120 per minute. In February, 1882, the legs had become œdematous, and there was marked analgesia in them, except on the soles of the feet, which were hyperalgesic; sensations of touch were, however, readily perceived. Though he had a sanguineous dysentery, there was no incontinence. On the 12th there developed suddenly great difficulty in respiration, due to suspension of all diaphragmatic breathing, and the next day he died. An ophthalmoscopic examination on the last day showed an atrophy of both optic nerves on the outer side of the eyes.

Autopsy: Brain and cord normal. No macroscopic changes in the nerves. A microscopic examination, however, showed the presence of a very high degree of degeneration and degenerative atrophy in the nerve-fibres. The myelin had divided in large and small drops containing fat-granules; the degenerated mass within the Schwann sheath, consisting of myelin and axis-cylinder, was seen in various stages of absorption, and in spots the empty Schwann sheath alone remained. No inflammatory exudation was present, and the endoneurium and perineurium appeared to be normal. The muscles showed evidence of degenerative atrophy. The anterior nerve-roots were normal.[2]

The lesion here resembled exactly that in Joffroy's case, already cited. It was similar in the following case.

Observation X.—Female, who had recently indulged in alcoholic excesses and had suffered from gastritis and delirium tremens; complained for some days of pain in her legs and numbness in hands and forearms. When seen by Dr. Webber the pains in the limbs were severe, and she could not turn in bed without help, her knees were drawn up, and attempts to straighten them caused pain. There was loss of power in extensors of the wrist and hands, and the fingers could not be shut perfectly. There was general tenderness over the muscles of the extremities, and pressure along the nerves was very painful. Her throat was sore, but she did not have diphtheria. She spoke in a whisper and with difficulty. Three days later anæsthesia of the feet and hands appeared, and the tendon reflexes were lost. The pain became so severe that morphine was given to control it. The paralysis became more complete, the anæsthesia increased, incontinence of urine and feces developed, she appeared to be very feeble, and respiration became wholly thoracic. Seventeen days after admission to the hospital she died.

Autopsy showed brain and cord normal. The chief nerve-trunks of the extremities, and the phrenic and pneumogastric were in a condition of degeneration, the distal ends being affected to a greater degree than the central portions. "The simplest change found was in the medullary sheath at Ranvier's constrictions, without break in the axis-cylinder, and without increase of nuclei." In some nerves extensive degeneration was found, the medullary sheath being broken up into fatty fragments, the axis-cylinder discontinuous or destroyed, and the number of nuclei increased. In the fibres which were most altered was found an increase of nuclei; and apparently small masses of protoplasm, not nuclei, were tinted in the midst of the granular débris. Nearer the root of the nerves axis-cylinders were more numerous. In the sciatic the sections from the highest part of the nerve, which had been preserved, were still diseased in a small proportion of their fibres.[1]

A very similar case, with the same changes in the nerves, is recorded by Müller.[2]

The following case, under my own care, terminated favorably.

Observation XI.—Male, aged thirty-six, a hard drinker, after an attack of gastritis became paralyzed suddenly in both legs. A few days after this, both hands became useless, so that he was completely helpless. His wife says that his memory is quite gone. On admission to Bellevue Hospital, September, 1880, seven weeks after the onset, he complained of pain in all four extremities, and of tenderness in the muscles and joints when these were handled. The upper extremities were almost totally paralyzed below the elbows, the only motion possible being a slight flexion of the fingers. There was wrist-drop on both sides. The lower extremities were totally paralyzed below the knee, and the feet hung down motionless. The muscles of the thighs were also affected, for although he could pull his legs up in bed, it was with great difficulty that they could be straightened out. All the paralyzed muscles were atrophied, and the faradic reaction was lost in the extensors and greatly diminished in the flexors. The galvanic reaction was not tested by me from lack of apparatus. Tactile sense was considerably impaired, but the senses of pain and temperature and muscular sense seemed to be natural. The knee-jerks were lost. When an attempt was made to have him stand, the feet were pushed out and the knees doubled under him at once. Fibrillary twitchings were very noticeable in the atrophied muscles, and a marked tremor of the tongue was seen. The facial and ocular muscles were not affected, and the special senses were normal. There was no incontinence of urine and no symptom of thoracic or visceral disease. His mind was much impaired. He talked in a rambling manner, laughed much, and could not fix his attention, and his memory was so poor that no reliance could be put in his statements. Under treatment by iodide of potash, and complete cutting off of all stimulants, he began at once to improve. In two months from the time of admission he was able to walk, and one month later he was discharged perfectly well.

These cases are sufficient to present a clinical picture of the symptoms and course of the forms of alcoholic multiple neuritis. The differential diagnosis, elements of prognosis, and means of treatment will be considered when other classes of the disease have been studied.

(*b*) *Multiple neuritis due to poisoning by arsenic.*] It has long been known that an occasional result of arsenical poisoning is the development of paralysis, but it is only within the past four years that the fact has been determined that the symptoms in these cases are due to an affection of the peripheral nerves. Had the fact of the peripheral origin of alcoholic paralysis not been already proven, it is probable that the theory so long in vogue, that arsenical nervous symptoms were due to spinal lesions, would still prevail. But there is such a similarity between the two sets of cases, that it is impossible to ascribe them to other than the same pathological condition. Autopsies in support of the position that the peripheral nerves are involved are few in number, but in several cases the lesion has been found. The observations on record of spinal lesions are, it is true, more numerous; but when these are compared it is found that different lesions have been discovered in different cases, so that there is no single pathological change in the spinal cord which is constantly produced by arsenic. Further, some of the changes described in experimental cases in animals (viz., vacuolization of cells) are due to imperfect hardening of the specimens. It must, therefore, be admitted that multiple neuritis may be due to arsenical poisoning.

The changes produced in the nerves are so exactly similar to those already described, that there is no need of a recital of the pathological process.

The nervous symptoms produced by arsenic have been thought to vary somewhat, according as the ingestion of the poison has been a sudden or a gradual one. Brissaud claims that if there is slow poisoning, as, for example, by the long-continued use of Fowler's solution, paralysis is rather the exception, and is not severe, it is diffuse and transient; while other symptoms, such as gastro-enteritis, trembling, delirium, and aphasia, attract the chief notice. If there is acute poisoning from an overdose of arsenic, he holds, on the other hand, that paralysis ensues either during the period of active symptoms of poisoning, or soon after. The observations of other equally careful authors do not entirely support this view of Brissaud; for in two cases of Dana, one of acute, the other of chronic poisoning, very similar symptoms of paralysis and ataxia developed.

The description which has been given of alcoholic paralysis might almost be repeated for arsenical paralysis. There is the same limitation of the affection to the muscles of the distal parts of the extremities, the extensors being chiefly affected, and the weak muscles are flaccid, soft, and atrophied. There is a partial reaction of degeneration. The tendon reflexes are abolished; skin reflexes are preserved. There is often a marked tremor. The paralysis may begin either in the feet or in the hands, is usually bilateral, but has been, in four cases, of the hemiplegic type. The same dropped wrist and dropped foot are seen as in alcoholic cases. Disturbances of sensibility are prominent symptoms; burning, tearing, shooting pains; formication, tingling, muscular, and arthritic pains and tenderness are associated with hyperæsthesia, and this may be followed by irregular patches of anæsthesia. The muscular sense is usually impaired, and so much so in some cases that an attempt has been made to establish a distinct class of cases as arsenical ataxia, or pseudo-tabes arsenicale. In these cases the incoördination of hands and feet, Romberg's symptom, and an awkward gait are very noticeable, so that tabes may be suspected until the history makes the causation evident. In a case of Dana's the patient could not tell the position of his limbs or distinguish between weights differing one to forty. In Scolozouboff's case the walk resembled that described by Westphal in alcoholic tabes, and was easily distinguished from a real ataxic gait. Seeligmüller and Dana, however, affirm that the gait in their cases was like that of locomotor ataxia. Occasionally œdema of the extremities, cyanosis, unusual sweating, and extensive desquamation indicate an implication of vasomotor and trophic nerve-fibres. In the most severe cases contractures in a flexed position developed in the paralyzed limbs. The sphincters are never involved. The duration of arsenical paralysis is somewhat greater than that of ataxia. Either condition may last several months, but occasionally the recovery is complete in a few weeks. Frequently, after the power has returned, the patient suffers for months from numbness and tingling in the extremities which are sufficient, as in a case under my own observation, to interfere with the finer motions, to disturb the sleep, and to cause constant discomfort. According to Gerhardt's statement (cited by Dana), ninety-seven per cent. recover wholly.

(*c*) *Multiple neuritis due to poisoning by lead.* It is not my purpose to enter upon any description of the various forms of lead palsy, which are familiar to every practitioner. Nor is this the proper place for a discussion regarding the various theories of the pathology of the disease. It is only necessary to call attention to the fact that there are now on record a number of autopsies in cases of lead paralysis in which the lesion has been found in the peripheral nerves. In a recently published case of Schultze[1] there was found a very marked atrophy and disappearance of nerve-fibres in the trunk of the musculo-spiral nerve, below the point where the branch to the supinator longus was given off. This decreased in intensity centrally, so that at the brachial plexus no anomaly was found. It increased in intensity toward the termination of the nerve in the muscles. The spinal cord was normal. This is simply a type of a number of recently published cases. On the other hand, there are numerous cases of this disease in which decided spinal lesions have been found, so numerous that many writers always ascribe the disease to destruction of certain groups of cells in the anterior cornua of the spinal cord. It must be admitted, therefore, that in lead we have a poison which, under certain circumstances, affects the spinal cord, and under other circumstances produces neutritis. It may be claimed that the same is true of alcohol and arsenic, and in showing that these poisons can cause neuritis there is no intention of defending the position that they never affect the central nervous system. But it is important to notice that the central or-

gans are rarely involved. The limitation of the neuritis in lead palsy to the motor nerves makes the clinical picture in some cases resemble closely that of spinal disease. In illustration of this the following case is cited:

Observation XII.—A male, aged thirty-six, by occupation a dyer, had suffered from numerous attacks of lead colic, followed by general muscular weakness, which on one or two occasions was so great as to be a general paralysis rather than a simple weakness, and had finally developed a paralysis of the extensors of arms and legs, when admitted to the hospital, where he spent the last three years of his life. During this time his paralysis varied somewhat in degree, but was never entirely recovered from. The muscles affected were the extensors of arms and legs. These were much atrophied, and showed a loss of faradic reaction, and a characteristic change in the galvanic reaction, the anode producing stronger contractions than the cathode, and all contractions being slow. There was also a considerable degree of œdema in the extremities, especially in the legs. Spasms in the unparalyzed flexors occurred on one occasion for one day. The patient suffered also from the symptoms of cardiac disease and phthisis, to which he finally succumbed.

The autopsy showed no changes in the brain or spinal cord. The muscular branches of the peripheral nerves, although presenting no macroscopic changes, were found in a state of extreme degeneration when examined microscopically. Side by side with normal fibres were to be seen fibres, unstained by osmic acid, wholly destitute of myelin sheath. There was no fatty degeneration. Between the fibres a thick, finely fibrillary connective tissue, with many cells, was found. Transverse sections of the nerve trunks showed a large number of small fibres scattered among the normal fibres, but not collected into bundles, and it was often difficult to distinguish naked axis-cylinders from connective-tissue fibres. The lesion was an increase in the connective tissue of the endoneurium with simple atrophy of the nerve fibres of different grades.[1]

But in a certain proportion of the cases of lead palsy there are marked sensory disturbances, consisting of severe pains, and anæsthesia, with numbness. In these it is possible, especially if tenderness along the nerves and in the muscles is present, to make the diagnosis of multiple neuritis. The history of the following case, under my care, coincides so closely with that of other toxic cases of neuritis that the diagnosis could not be mistaken.

Observation XIII.—Male, aged thirty-eight, after suffering from an attack of lead colic, began to feel numbness and pain in his legs and feet, which soon extended to his hands and forearms. This steadily increased for two weeks, and to it was added paralysis of the extensors of both hands and both feet, so that at the end of that time he was unable to use his hands or to stand. With the paralysis there was a rapid atrophy of the muscles, and a decline in the faradic excitability. The muscles became more and more tender, and the spontaneous pains gradually increased until it was necessary to use opium freely to quiet them. By the end of a month a well-marked anæsthesia had developed below the knees, and it was noticed that the atrophied muscles were in a constant tremor. There were wrist-drop and foot-drop on both sides, and all reaction to faradism ceased. It required a very strong galvanic current to produce contraction and ACC was greater than KCC. The knee jerk was preserved. The muscular sense was impaired. For five months his condition remained stationary, in spite of treatment by strychnia, iodide of potash, massage, and electricity. Then a gradual improvement set in, the pains became less severe, sensation returned, the muscles regained their contour and strength, and, finally, the electric contractility returned to the normal standard. About a year from the onset of the symptoms the recovery was complete.

[illegible] *carbon*[1] *and from illuminating gas* has been suspected, and the similarity of the symptoms in such cases to those already described is quite remarkable. But as there are no autopsies to substantiate the theory, this cause is merely mentioned.

ORIGINAL ARTICLES.

IS THE DANGER FROM POST-PARTUM HEMORRHAGE INCREASED BY THE USE OF ANÆSTHETICS DURING PARTURITION?[2]

BY [illegible] PARKER, M.D., LL.D.,
[illegible] New York.

The affirmative answer to the question which forms the title of this paper was one of the most effective arguments urged against the use of anæsthetics in midwifery nearly forty years ago by men of such obstetrical eminence as Tyler Smith, Robert Barnes, and many others. It carried great weight, as it seemed obvious that an agent which paralyzed sensation, and, if carried to its full effect, equally paralyzed voluntary motion, must inevitably arrest that muscular contractility which is the essential condition for preventing post-partum hemorrhage.

The influence of this impression is seen in the fact that nearly all works on obstetrics, even by the most recent authors and many writers in medical journals, refer to the danger of anæsthetics in causing post-partum hemorrhage. Barnes, for example, speaks of anæsthesia induced by chloroform or ether, as among the most efficient causes of post-partum hemorrhage.

These warnings work for good in so far as they lead obstetricians to take those precautions which I believe to be a duty in every labor, to prevent this appalling accident, for it is my firm belief that no woman under the care of a watchful, prudent, and competent obstetrician ever ought to die from post-partum hemorrhage, due solely to uterine inertia or ataxy.

This paper will only refer to hemorrhage from this cause, as no one will assume that anæsthetics can produce those local lesions which we all know sometimes cause terrific and even fatal hemorrhage.

[1] Ross: Medical Chronicle, January, 1887.

[2] Read before the Medical Society of the State of New York, Albany, February 1, 1887.

No one can doubt that either chloroform or ether may be given to the extent so far beyond anæsthesia as to induce profound narcosis, or that, if the uterus be suddenly evacuated while in this condition, there would be a temporary paralysis of the organ with a loss of power to contract and close the open mouths of the uteroplacental vessels.

The real question is whether anæsthetics, properly administered, should be withheld from a woman in labor, when desirable to save her from unnecessary suffering, on account of the danger of their causing post-partum hemorrhage.

I may here say that I have long regarded chloroform as the best and safest anæsthetic in obstetrics, and that since 1850 I have used no other.

My reasons for this preference are briefly these:

1st. Its odor is to most persons much more agreeable, and it is much less persistent. When sulphuric ether is used, it frequently, at first, produces more or less irritation of the fauces and bronchi and an annoying cough or choking is excited. The effect of this is bad, both on the patient and on the surrounding friends. It excites apprehension which more or less tends to counteract the influence of the agent.

2d. The influence of chloroform is much more rapid and a much less quantity of this agent is required than of the ether. We are thus saved, in a great majority of cases, the preliminary stage of excitement which the ether produces, and we are able to use the chloroform for each recurring pain, the patient in the interval being comparatively free from the influence of the anæsthetic. Thus, in the aggregate, not only is a much less quantity of the agent required, but the patient is exposed to the danger from the anæsthetic, if any danger there be, for a much shorter period of time.

3d. By chloroform we are able to regulate the degree to which we may desire to carry anæsthesia with a certainty and security that are not possible with the ether.

4th. The danger from anæsthesia by ether, where disease of the kidney exists, first pointed out by my friend Dr. Thomas Addis Emmet, and now confirmed by several observers, has not been noted by any one as resulting from the use of chloroform.

We all know that the great security against post-partum hemorrhage lies in the efficient and permanent contraction of the uterus after delivery.

While we are constantly meeting in obstetrical literature with the statement that the danger of post-partum hemorrhage is increased by the use of anæsthetics, I have never been able to find any statistical evidence in proof of the assertion. What is termed uterine inertia is often but another name for uterine exhaustion, and this must certainly be much less likely to occur when the nerve force and vital powers have been saved by the use of an anæsthetic.

This uterine exhaustion may be and often is the result of a prolonged labor, and while I am convinced that the effect of chloroform is often to prolong labor, I have not been satisfied that this apparent objection was not more than counterbalanced by the advantages obtained by its use, even where the use of the forceps has been made necessary from this cause.

But in a large majority of patients my experience would lead me to the conviction that the use of chloroform shortens the labor. I am certain that it does in all those cases where the pains are diminished or suspended by extreme sensitiveness and fear of pain, by vivid moral impressions or hysteria, or by pains resulting from the coincidence of some malady, either existing antecedent to, or appearing during labor, such as rheumatism of the uterus, or other muscular tissues, or sharp pains in the back or abdomen distinct from the pains from uterine contractions, gripings in the intestines, or the cramps which are occasionally produced by the pressure of the child's head on the sacral nerves; and, finally, in all those cases where inefficient uterine action results from loss of sleep and extreme exhaustion from a prolonged first stage; and in many cases where the labor is retarded by rigidity of the os uteri or perineum. Thus, on the whole, I am obliged to state my conviction that chloroform accelerates labor in a greater proportion of cases than it retards it.

I have attended a number of patients who in previous labors have had their lives endangered by post-partum hemorrhages, and who were placed under my care for this reason. All these cases I have watched with the greatest anxiety, and have endeavored to see that they were in such a condition as would best prevent the occurrence of this accident after delivery. On questioning them or their intimate friends, or, where practicable, their former medical attendant, I have learned that their previous labors have almost invariably been followed by great prostration, and that when labor was completed they were in a state of almost extreme exhaustion. A peculiar idiosyncrasy, or a former tendency to hemorrhage, or an extreme feebleness of the patient, has been assigned as the reason why chloroform had not been given in former labors; the very reasons why I should consider this anæsthetic, properly and watchfully administered, as especially indicated. Such patients have generally remarked to me, when they have come out from the influence of the anæsthetic, "How different I am from what I ever was before, after confinement." They take nourishment and stimulants, if need be, and I then feel warranted in assuring them that all danger of "flooding" has passed, but I never leave them until I am certain of the fact. When I do leave, I give emphatic directions to the nurse for close watching and minute instructions as to what she shall do if there be the least threatening of hemorrhage.

Some years ago, this subject came up for discussion incidentally before the American Gynecological Society,[1] in which one of my most valued friends, and certainly one of the most able writers on certain obstetrical subjects, expressed great surprise at statements of mine like those just made, for the previous winter I had been called to see a case in consultation with him on account of post-partum hemorrhage, which he regarded as due to the inhalation of chloroform. At the time, from the history then given, it was my conviction that the hemorrhage was the

[1] Transactions, vol. [illegible].

result of a very inefficient and partial use of the anæsthetic, as the patient, a very nervous, excitable woman, was extremely intolerant of pain, and, in consequence, she was never aided by the accessory muscles—and after several hours he was obliged to use the forceps. The hemorrhage which followed was the result of uterine exhaustion, due partly to emotional causes and partly to the fatigue of a prolonged labor. Three years after, by reason of the death of my friend, I attended this same patient in her second confinement. She was so sensitive to pain which bore no relation to the force of the uterine contractions, that, early in the labor, I gave her ten drops of Magendie's solution with the effect of quieting her, but regular labor pains did not follow.

She was extremely apprehensive of danger from the inhalation of chloroform. After watching her ineffective labor for some hours, I persuaded her to make only one full inspiration of chloroform to relieve the next pain. She was ready to make two inspirations with the next, and three with the next, and soon came under its full influence during the pains, but was perfectly conscious for a moment or two during the intervals, until with the return of a pain she would very impatiently call for the chloroform. After this the labor went on regularly and rapidly, so that the child was born within one hour after she commenced the inhalation of the chloroform, and the delivery was followed by perfect uterine contractions and no hemorrhage. Her convalescence was in every respect most satisfactory.

In the discussion alluded to, my friend expressed the opinion that danger of hemorrhage did not follow the use of sulphuric ether. I have never seen hemorrhage follow the use of either agent (I have never used ether in obstetric practice since 1850), but I should reason *a priori*, that an agent which paralyzed the nerves of the uterus and thus prevented its permanent contraction, would be dangerous in exact ratio with the continuousness of the effect, and that an agent, the extent of the anæsthesia from which is perfectly under the control of the administrator, the effect of which is intermittent and which is only used during the time of pain, would be safer.

The danger of post-partum hemorrhage in patients with cardiac disease is known to all. It seems to be almost accepted as an axiom with both the profession and public, that the inhalation of chloroform is dangerous for any woman with "disease of the heart."

For more than thirty years I have been convinced that this opinion is quite erroneous, and I have so taught in my lectures and in former writings.

In March, 1853, I was called to see the wife of a physician in this city in her fifth labor. I had seen her once before, the latter part of the previous December, with the late Professor Chandler R. Gilman, to decide as to the propriety of the induction of premature labor, as she was suffering from severe cardiac troubles.

She had been repeatedly examined by Dr. Alonzo Clark, whose diagnosis was, great dilatation of the left ventricle and mitral insufficiency. We were then in full accord that the induction of premature labor would be unsafe. When labor came on, I was sent for, as Dr. Gilman was ill. When I saw her she had been in the second stage of labor, as her husband said, about one hour. The first stage had been nearly four hours, unattended by any symptoms to cause grave anxiety, but when the expulsive pains began, her condition became rapidly bad. Each pain, which recurred every six minutes, caused faintness, nausea, and slight vomiting, but the pains were much more severe in the chest than in the uterus. Her appearance was appalling, the countenance was extremely pallid, the lips and fingers were cyanosed, the face was covered with large drops of perspiration, and the pulse very weak and irregular. The os was nearly dilated, very soft and yielding, the membranes protruding, but the pains very ineffective. After watching her for a few moments, I regarded her condition as perfectly hopeless and proposed chloroform, solely in my own mind, with the hope of euthanasia. Her husband would not consent to this, making the objection that she could not bear an anæsthetic, as she had once inhaled ether to have a couple of teeth extracted, with very dangerous results. I then gave her five drops of Magendie's solution of morphia, which was followed for a time by some improvement. But soon after her condition became as bad as before, until I could not bear to witness her suffering any longer and avowed my intention of leaving, as I could be of no service. Her husband begged me to stay, adding, "Do what you think best and God help you."

The few moments that we had to wait before the chloroform could be obtained, seemed to me so many hours, which I passed in trying to get her to swallow some brandy and water, to which she had a great aversion, and in explaining to her exactly *how* I wished her to inhale the chloroform; I began by giving a few whiffs first, as an impending pain was apparent, gradually increasing the amount until she became unconscious during the pains. She was always conscious some time during the interval between each pain.

After a short time, a wonderful change was apparent, her pulse became regular and stronger, while her husband, who frequently counted it, said that it never exceeded 96 a minute; while, before my arrival, it had been 140 in the intervals, but could not be counted during the pains. Her countenance improved in color, and assumed a most placid, contented expression.

During the pains there was no voluntary assistance on the part of the patient, and but slight aid from the accessory muscles. After she had been taking the chloroform an hour the membranes ruptured, and finding the head low down in the pelvic cavity, the position favorable, and the soft parts yielding, I said to the husband, "What is the use of letting her suffer more fatigue? The forceps can be applied with great ease, and may shorten the labor two or three hours." It was applied, without changing her position in the bed, and in a few minutes she was delivered of a living girl, weighing six pounds and a half. She made a very good convalescence.

In January, 1856, I again attended this lady in

confinement. For the three months previous, I had seen her often and had endeavored to lessen the labor of the heart by improving the character of the blood which it circulates by such medicines as the tincture of the chloride of iron, the chlorate of potassium, and digitalis. The labor was short and comparatively easy under chloroform and delivery by the forceps. She outlived her husband three years, but died in July, 1860, from Bright's disease and her cardiac troubles.

Since this case I have seen several others in which labor was dangerously complicated with heart troubles, and which terminated favorably, as I think, solely from the use of chloroform.[1]

So far as I know, these views which I have long taught, have been advocated by no author until the publication of the valuable work by Dr. Angus MacDonald, of Edinburgh, in 1878. His explanation of how the uterine contractions of the second stage, where heart trouble exists, cause the dangerous symptoms of violent palpitation, dyspnœa, syncope, etc., is most satisfactory to my mind.

An interesting paper on this subject by Dr. J. L. Owen, appeared in the *New Orleans Medical and Surgical Journal*, in 1881.

There are so many important papers to be read before the Society that it would be wrong for me to occupy its time longer. I will, therefore, close with a statement of my personal experience in the use of chloroform in parturition.

During the past thirty-seven years I have rarely attended a woman in confinement without the use of chloroform—never where she has suffered considerable pain. Having thus used it, in several thousand cases, I unhesitatingly assert that not in a single case have I ever found reason to regret its use.

In addition to my own experience, I have carefully watched for all that has been published on this sub ject, and I am fully in accord with an eminent authority on obstetric anæsthesia, Dr. J. B. Reeve,[2] of Dayton, Ohio, in his assertion that

"The most rigid scrutiny, inspired by hostility, has failed to show that, when judiciously used, it exerts any injurious influence on the mother or child.

"Chloroform has been used in natural labor many hundred thousands of times, yet but a single case of death is on record, when it was administered by a competent medical man, and in this there is lack of post-mortem confirmation."

I would add, that in this case the death was preceded by a convulsion.

In my private practice, I have never had but one case of post-partum hemorrhage, and in this no anæsthetic had been used, as the child was born within five minutes after I entered the room, before I had time to make any examination, and a terrific flooding followed.

[1] I find the following sentences in the most recent work on obstetrics, a most interesting and valuable text-book by Dr. Parvin.

"Vergeley, quoted by Dutertre, states that cardiac diseases do not forbid the use of an anæsthetic in labor, and chloroform acts as a sedative in these affections, and may be given prudently. Barr believes that obstetric anæsthesia has a beneficial sedative action upon the heart." (Science and Art of Obstetrics, by Theophilus Parvin, M.D., LL.D., page 232. Phila., 1886.)

LARGE DOSES OF IODIDE OF POTASSIUM IN A CASE OF PROBABLY SPECIFIC BRAIN TUMOR.

By B. L. MILLIKIN, M.D.,

OPHTHALMIC AND AURAL SURGEON TO ST. JOSEPH'S AND ST. ALEXIS HOSPITALS, CLEVELAND, O.

M. J. K., aged sixteen, applied to me November 24, 1885, with the following history: When a child she was struck in the right eye, and has never been able to see out of it since, and now has barely light-perception. The left eye has failed so that she has not been able to read for the past two months. She states that once before she lost the sight of the left eye, so that she could not read, but the vision came back slowly, and after a period of six weeks she could read again.

The following is all the family history she knows: Supposes her father is living, but she has heard nothing of him for seven years; mother died of consumption several years since; had two brothers, both dying in infancy, one of "consumption," and one sister living and healthy. The patient herself is a stout, dark-haired, florid, well-nourished, well-developed girl. States that she has never menstruated. For two or three years past she has had violent attacks of headache, coming on two or three times weekly, accompanied with vomiting. For the past two months she thinks the headaches have not been so severe, but the failure of vision has come on with the subsidence of pain. She has somewhat of a staggering gait in walking, and often has dizzy spells. The ophthalmoscope shows extensive choroidal changes in various parts of the fundus of the right eye, and particularly in the macular region; atrophic changes of the optic disk, arteries thread-like, and a hypermetropia of about 7 D. In the left eye the disk is swollen, edges obscure, the vessels embedded in the œdematous papilla, and the mediæ slightly hazy; hypermetropia of 3 D.; no choroidal changes. Vision equals $\frac{0}{36}$.

Two weeks later, December 11th, the patient was admitted into Charity Hospital, when vision had so far diminished that she had only light-perception in either eye; patellar reflex was very much decreased, and the difficulty in walking had greatly increased. She would stagger about, having a tendency to fall, and had frequent dizzy spells. Potassium iodide, gr v, and hydrarg. bichloridi, gr. $\frac{1}{16}$, three times daily, were administered, the dose to be increased.

By the early part of January, 1886, the gait had become so much affected that she could not walk alone without falling, and frequently had attacks of tremulousness in which she fell to the floor, but did not have a regular convulsion, nor did she ever lose consciousness. These attacks were often very frequent, coming on several times a day. After these there was generally a good deal of pain over and back of the right eye.

The case continued in about this condition, or perhaps slowly became worse, until the latter part of January. At this time there appeared upon the right side of the head, and a little later upon the left side, in front of and a little above the ear, extending

from the zygoma upward into the temporal region, a peculiar swelling which rapidly increased. This gave a feeling like that of fluid under the periosteum, and, when pressed upon, a peculiar crepitant sensation like a soft-shelled egg when indented, or like parchment. When this swelling was pressed upon with the finger, and the finger suddenly removed, it returned to its original form with a sharp snap which could be distinctly heard at a distance of several feet. This condition lasted several weeks, and then slowly disappeared, subsiding entirely, leaving the region in its normal condition. Until the middle of March the condition of the patient remained much the same, or she became slightly worse. The general health was somewhat affected, she became pale, and her appetite impaired. The mercury had been continued until the gums were slightly touched, and tonics and good diet administered. The papilla of the left eye gradually but surely passed through the stages of optic neuritis, and terminated in an atrophic condition, with thread-like arteries, pale, contracted disk, and hopeless blindness.

Moderate doses of iodide of potassium and mercury pushed to its physiological indications not having produced any decided improvement by May 1st, I decided to push the iodide of potassium to the limit of tolerance. However, for ten days or two weeks before this, there had not been quite so much headache, and the nausea and vomiting had somewhat diminished. On May 3d the patient was ordered thirty grains of iodide of potassium three times daily, in plenty of water half an hour before her meals, the dose to be increased by five grains each succeeding day. By May 6th the dose had reached forty-five grains, and, as there were no indications of iodism, the dose was ordered to be increased by ten grains daily. By May 14th the patient had reached ʒij three times daily, with no iodism, and the dose was ordered to be increased by twenty grains daily. This was continued until the patient was taking ʒiij three times daily. By this time the potassium had produced some gastric irritation, and the patient complained of cramp-like pains in the stomach when the medicine was omitted. No other evidence of iodism appeared, except that the flow of saliva had slightly increased. From this time on the patient very materially improved in every way except vision, the restoration of which we had not hoped for. Until the present time there has been no return of the symptoms. She has had no headache, no vomiting, no staggering of the gait in walking, no attacks of tremulousness or dizziness; general health is excellent, and she feels in every way well. Her menstrual function has been established within the last two months. Her patellar reflex, however, remains somewhat diminished, and the optic atrophy is almost complete.

I call attention to this case with a twofold purpose. First, for the interest which is attached to the history of the case itself; and, second, as showing the extent to which the iodide of potassium may be pushed without deleterious effects.

The frequently recurring attacks of headache usually located in the right frontal region, the vomiting, the unsteadiness of the gait with attacks of tremors, and a disposition to fall, the development of optic neuritis terminating in progressive atrophy, and rapid and complete loss of sight, all point unmistakably to a tumor of the brain. Of the cause and location of the tumor we have no certain knowledge. Two points, however, strongly indicate a specific origin. The first is the family history, and the second is the therapeutic test. While the tolerance of large doses of the iodides does not infallibly demonstrate a specific state of the system the presumption in favor of this view is very strong.

So good an authority as H. C. Wood,[3] states that "if sixty grains of iodide of potassium per day fail to produce iodism, for all practical purposes, the person may be considered a syphilitic." Besides, another recent authority[4] states that "of all brain diseases occurring between the ages of twenty-five and forty years, probably eighty per cent. are due to syphilis." It would have been an easy matter for this case to have been infected in childhood, and, considering the uncertain moral element surrounding her youth, it is not at all improbable. One point which should be emphasized in connection with brain tumors, is the very frequent involvement of the visual apparatus.

In an article on "Brain Tumors" in Pepper's *System of Medicine*, Drs. Mills and Lloyd report a series of one hundred cases of tumors of the brain in which autopsies were made and the tumors located. Of these one hundred cases, fifty-one had impairment of vision or optic neuritis, and twenty-six had some affection of the muscular appendages of the eye. In other words, no less than seventy-seven per cent. of these cases showed decided eye symptoms, while several others either died suddenly, leaving no opportunity for an examination, or else the eye symptoms were not noted.

The most interesting feature of this case, however, has been the remarkable tolerance of the iodide of potassium. So far as I have been able to find in the literature on the subject, at my disposal, no such dosage has been reported. While there is little or no danger of death from this salt, yet the symptoms often engendered by it are so disagreeable and annoying as not to be desirable.

In the cases[5] where death has occurred after the administration of this salt, it has been used in combination with the chloride, which together form an irritant and poisonous iodate of potassium. H. C. Wood[4] recommends the iodide in doses of one to three drachms daily in cases of syphilitic affections of the brain, while Bumstead[5] states that he has given as high as two drachms three times daily with impunity.

De Wecker[6] urges the use of large doses if smaller ones do not produce the desired effect, and advises ten to twelve grammes (154–186 grains) to be given daily.

The U. S. Dispensatory[7] states that the dose may

[illegible]

[illegible]

[illegible]

be up to six drachms daily, and that Dr. Buchanan, of Glasgow, has given half an ounce at a single dose with no deleterious effect, but this latter dosage was not continued for any length of time.

The lesson we may learn in this connection is, that whenever tertiary syphilis is present in any form, and we do not get satisfactory results from small or moderate doses of the iodide of potassium, the case should not receive an unfavorable prognosis until this salt has been pushed to the utmost limit of its physiological tolerance. We will often get surprising results from this method, and not to be obtained in any other way.

In the administration of the iodide of potassium the use of the following formula will be found convenient:

℞.—Potassii iodidi . . . . . ʒj.
Aquæ distillat. . . q. s. ad ʒj.—M.

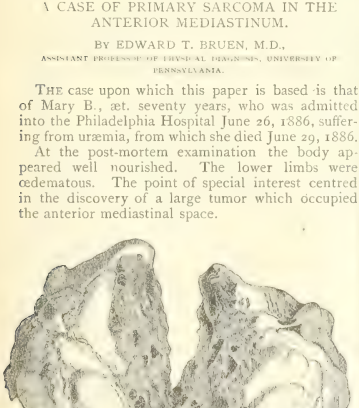
Of this solution one minim equals one grain of the salt, but it should be remembered, however, that one minim equals about two drops. The disagreeable taste is best concealed by adding to the dose one or two teaspoonfuls of the compound syrup of sarsaparilla, and it should always be freely diluted with water.

A CASE OF PRIMARY SARCOMA IN THE ANTERIOR MEDIASTINUM.

By EDWARD T. BRUEN, M.D.,
Assistant Professor of Physical Diagnosis, University of Pennsylvania.

The case upon which this paper is based is that of Mary B., æt. seventy years, who was admitted into the Philadelphia Hospital June 26, 1886, suffering from uræmia, from which she died June 29, 1886.

At the post-mortem examination the body appeared well nourished. The lower limbs were œdematous. The point of special interest centred in the discovery of a large tumor which occupied the anterior mediastinal space.



The mass weighed fourteen ounces, it was six inches long by five inches broad and four inches in diameter. It was about the size and shape of the average normal heart. It presented a reddish-white, fleshy appearance, and was quite soft and pulpy in consistence. The tumor was situated immediately behind the upper piece of the sternum. It consequently overlaid the aorta and pulmonary artery with the other structures lying in the deeper mediastinal spaces—it also encroached upon the left thoracic cavity. The upper lobe of the left lung was pushed aside by the mass in a direction outward and backward. The lobe was splenified and the lower lobes of the lungs on both sides were somewhat congested. There were only a few slight adhesions between the tumor and the visceral layer of the pleura of the upper lobe of the left lung. The tumor was not in any manner attached to the sternal or costal bones. The bronchial glands in the anterior mediastinum were slightly enlarged, but the glands at the roots of the lungs were normal. The remaining structures in the thorax, including the heart, were normal. The kidneys presented the usual appearances characteristic of the granular contracted organ. The capsules were adherent and numerous cysts studded the cortical portions. The uterus was covered with fibroid growths, and the ovaries were calcified. The liver and spleen, with the other abdominal viscera, were carefully examined, but nothing of an abnormal character could be discovered. A biliary concretion was found embedded in the intestinal mucous membrane just below the opening of the gall-ducts. The brain and its membranes were examined, but nothing of an abnormal character was detected.

The specimen is, therefore, of special interest because it is an example of a case of primary sarcoma of large size located in the anterior mediastinum without any secondary formation. As already stated, none of the lymphatics in the mediastinum were enlarged, and the growth seemed to have originated in the pleura of the anterior mediastinum. The results of microscopic examination would class this tumor with the small round-celled sarcomata with a tendency to alveolar formation.

The clinical features peculiar to this case, although by no means unique, yet deserve consideration:

1st. The morbid growths in this region of the body are usually sarcomatous.

2d. The age of the patient, which was advanced, is an unusual and yet recorded coincidence in tumors of a sarcomatous nature in this location.

3d. The absence of wasting and cachexia. The patient's appearance was that of a person in average health. This peculiarity is also not remarkably exceptional in this class of cases.

4th. The almost entire absence of any subjective symptoms pointing to the morbid growth. The patient was under observation but a few days before her death. She complained of slight cough and dyspnœa, and auscultation of the chest revealed feeble respiration over the posterior portions of both lungs, also anteriorly over the left apex.

There was dulness on percussion over the sternum, and some four finger-breadths to the left of the sternal margin; but when these physical signs were detected the patient was near her death, and their true significance was not established

The patient came to the hospital for treatment of symptoms which were plainly dependent upon renal disease, such as albumen with casts in the urine; increased arterial tension; with nervous symptoms

usual to uræmia, which was the immediate cause of death. As the patient had worked as a domestic until shortly before applying to the hospital, it is fair to assume that there were no important subjective symptoms to call attention to the thoracic mischief.

5th. The foregoing statement is in consonance with the history of anterior mediastinal growths, which are much less likely to occasion severe pressure symptoms than tumors originating in the other mediastinal regions.

6th. While the diagnosis in this case was not established during life, and while the case represents very forcibly the slight disturbance of the economy which may accompany certain of these mediastinal growths, and particularly those occupying the anterior mediastinum, yet it is quite probable that had there been opportunity for a more thorough and prolonged study, the diagnosis might have been established. The dulness over the left sternal region, the distant and feeble heart sounds and weak respiratory murmur over the left apex with the dyspnœa were certainly suggestive symptoms.

MEDICAL PROGRESS.

ASEPTOL: A NEW DISINFECTANT.—This substance is orthophenol-sulphuric acid, and has been known since the year 1841. It has been lately brought forward in France as a disinfectant, and Dr. Hüppe (*Centralb. f. d. Med. Wiss.*, No. 50, 1886) has made experiments with it, which have led him to the opinion that it possesses advantages entitling it to rank beside carbolic acid and bichloride of mercury. Commercial aseptol is a syrupy liquid, having a faint odor of carbolic acid. It is soluble in all proportions in water, alcohol, and glycerine, and even in a 10 per cent. solution has no caustic action upon the skin. Such a solution kills spores of anthrax in thirty minutes, whilst a 5 per cent. carbolic acid solution requires at least twenty-four hours to produce the same effect. A 3 or 5 per cent. solution of aseptol is a true disinfectant for spore-free microörganisms, or for such as do not form endogenous spores. A 3 per cent. solution was found quite sufficient to disinfect the (previously cleaned) hands. Solution of aseptol in alcohol, glycerine, or oil (in the last named no permanent solution takes place) showed no disinfectant power. By heat it is changed into the corresponding para-combination.—*British Medical Journal*, Jan. 1, 1887.

POISONING BY MUSHROOMS.—After mentioning the poisonous substances which have been found in the deadly variety of these plants, BENGNIES-CORBEAU describes the treatment of poisoning which occurs from their ingestion as follows:

The emptying of the intestines, by ipecac or castor oil. Stimulants, warmth, and friction. Subcutaneous injections of ether have been of great service.

The use of the following has also been beneficial:

Ammonii acetat.	℥ij.
Aquæ chloroformi	℥j.
Tr. opii	gtt l.
Syrup. menthæ piperit.	℥ss.
Aquæ	℥vjss.—M.

Tablespoonful every half hour, or hour, as needed. Also,

Syrup. morphiæ	℥x.
Syrup. ætheris	℥v.
Aquæ	℥vij.—M.

Tablespoonful every hour.

The administration of isolating and neutralizing remedies: among these are albuminous liquids; milk; lemonade, containing eight grains of tannin to the quart, or fifteen grains of iodide of potassium.

As physiological antidotes, we find muscarine and atropine, administered in the order named, and in doses to secure the full physiological effect these remedies offer the best hopes in treatment.

Siccard has treated dogs by subcutaneous injection of pilocarpine in doses of one-sixth of a grain, supplemented by energetic friction; the injection was repeated in half an hour, given over the heart. As soon as deglutition was possible, a drink of marshmallow water and potassium nitrate was freely given. Recovery followed this treatment.—*Revue de Thérapeutique*, January 18, 1887.

ANTI-PARASITIC INJECTION FOR BLENNORRHŒA.—DELPECH treats blennorrhœa with the following injection:

Peptone, mercurial	gr. ¾.
Aquæ destill.	℥vj.

Injection is made, morning and night, as follows: the liquid is twice injected and at once expelled; the third time it is allowed to remain two minutes. The peptone compound employed is one-fourth part sublimate.—*Les Nouveaux Remèdes*, December 24, 1886.

A NEW "CURE FOR CANCER."—DR. VELLOSO lays claim to having cured several cases of epithelioma of the face and lips with the juice of alvelos, a plant which belongs to the family of Euphorbiaceæ. It acted as an irritant, and destroyed the diseased tissue, which was quickly replaced by healthy granulations. Of the three different kinds of alvelos (male, female, and wild), the second is considered the most efficacious. It is found at Pernambuco, and although the natives have employed the juice for some time, it has not come into extensive use on account of the severe pain which it causes. The best results were obtained with the juice in a concentrated solid form, and with the addition of vaseline or lanoline. This preparation should be applied with a brush to the affected part (previously washed with a solution of carbolic acid), which should then be left exposed to the air for at least an hour. It should afterward be covered with lint. This treatment should, as a rule, be repeated every two or three days, and never more than once in twenty-four hours, as the pain of the application is severe. The treatment was more speedily successful when begun before ulceration had occurred.—*British Medical Journal*, Jan. 1, 1887.

MICROÖRGANISMS IN THE BLOOD; SPREAD OF EPIDEMICS.—An important paper was published by Wysokowitsch on the fate of microörganisms when injected into the body of warm-blooded animals. In 1874, Traube and Gscheidlen found that, if a quantity of putrid fluid were injected into the blood of rabbits and dogs, and the blood taken twenty-four hours later, with

aseptic precautions, no organisms developed in it, showing that the bacteria introduced had disappeared from the blood, or had been destroyed in it in that short time. Some years later, Watson Cheyne found also that saprophytic bacteria, when injected into the blood-stream of rabbits, disappeared from the blood in twenty-four or forty-eight hours, and he concluded that they had been destroyed in it. Pursuing the subject further, he found that if larger quantities were introduced, along with the fluid in which they grew, they were able to survive for a longer time, and that the same was the case with smaller quantities, if the animals experimented on had been previously weakened in health by the administration of repeated doses of phosphorus or other poisons. He explained this fact on the supposition that the products introduced with the larger quantities of putrefying fluid, or the poisons previously administered, had so weakened the vitality of the blood and tissues that they were no longer able to destroy the bacteria. Wyssokowitsch has repeated the experiments, and has come in the main to the same conclusions as Watson Cheyne, but he has added several interesting observations. In the previous researches, mixtures of bacteria, probably not containing spores, were employed; but Wyssokowitsch used pure cultivations of known organisms, and found that, while sporeless bacteria were rapidly destroyed, the spores could retain their vitality in the body for a long time, and remained in the tissues in a dormant state. In both cases, the blood very rapidly became freed from organisms, but the spores were deposited chiefly in the liver, spleen, and medulla of bone, and were apparently taken up by the endothelial cells of the capillaries, in which they were found embedded many days after their introduction. In one case a few spores of bacillus subtilis were found alive in the liver seventy-eight days after their injection, although none was present in the other tissues or organs. Wyssokwitsch's results with pathogenic organisms are very interesting. When only a few anthrax bacilli were injected, they disappeared from the blood almost completely for some hours, but after twenty-four hours they began to appear again, and increased in number till the death of the animal. When they were introduced in large numbers, this disappearance from the blood was not very marked. Apparently all bacteria tend to be deposited in the organs before mentioned, and in the case of non-pathogenic organisms are there rapidly destroyed unless spores are present. In the case of pathogenic bacteria, this deposit and destruction of the organisms is incomplete, and they very soon gain the upper hand, and again spread into and multiply in the blood. We have thus in the structure of the vascular walls, and especially in the endothelial cells of the capillaries, a protective arrangement against any bacteria which may find their way into the blood, These organisms are deposited and retained in or between the endothelial cells of the capillaries, especially in the organs in which the circulation of the blood is slowest. Then begins a battle between the cells and the bacteria, which results either in the destruction of the bacteria or of the cells, which in the latter case provide a pabulum for the further development of the organisms. Those bacteria which, as a rule, gain the victory must be looked on as specific bacteria, pathogenic for the class of animal experimented on.

Although in many cases it is now definitely proved that the microörganisms present are the cause of the disease, very little is known as to the modes of infection and the spread of epidemics, and accordingly the attention of several investigators has been attracted to this question. In the case of several diseases, such as anthrax, typhoid fever, cholera, etc., Pettenkofer has strongly advocated their relation to the soil. He holds that a certain local and seasonable condition is essential to the spread of these diseases, and finds these two factors in a porous material, the soil penetrable by air and water, and soaked with organic substances (local predisposition), and in variations in the moisture and temperature (seasonal predisposition). He teaches that the so-called contagious miasmatic infective diseases are in reality true miasmatic or soil affections. The virus is formed outside the body. The virus, x, leaves the body in an inactive condition; outside the body, in the ground or in a suitable substitute, something, y, is added to this inactive germ, and out of this combination, which occurs only outside the body, that is, out of x and y, is formed the infective germ z. That this supposition is in part wrong, is now proved as regards anthrax and cholera, by the fact that the intestinal discharges from animals suffering from these diseases are capable of giving rise to them in another animal, showing that the infective material leaves the body in a thoroughly active condition. Nevertheless, when these and other similar diseases occur in an epidemic form, it must be admitted that there is some relation between the soil and temperature, and the spread of the disease. What this relation is has been the subject of investigation by Soyka, Hueppe, and others. Soyka has examined the relation of bacteria to soil, taking especial note of the effect of moisture, temperature, and air. He finds that when anthrax bacilli are placed on soil they rapidly develop spores, and thus provide for their future propagation, and that the rapidity and certainty with which this occurs depend on the degree of moisture, on the temperature, and on the access of air. The necessary conditions are present in nature during the greater part of the year, and it is in this way that the soil is so essential to the spread of this disease. For were it not for this effect of the soil, these bacilli would soon die out because they are quickly destroyed by the ordinary saprophytic bacteria, if they are not in the spore condition. The soil acts then not by adding to their virulence, but by providing against their destruction. Hueppe has made a special study of this matter in reference chiefly to an epidemic affection of deer caused by a small bacterium. Here Hueppe found that the only relation to the soil was, that the infection was generally intestinal, that the bacteria could vegetate luxuriantly outside the body, and were not killed in passing through the stomach. Pettenkofer looks on inhalation as the chief mode of infection, and in fact disregards infection through drinking-water. The researches of Hueppe and Soyka show that in this he is wrong, and that infection occurs probably most often through the food and drink. Each disease seems to have its special mode of infection, depending on the biological characters of the microörganism which causes it.—*British Med. Journal*, December 25, 1886.

Myoctonine.—The *Journal de Medecine de Paris* publishes the following note on myoctonine. Myocto-

nine is one of the two substances extracted from aconitum lycoctonum by MM. Dragendorff and Spohn. It is a yellow, bitter, amorphous body, having for its formula $C_{37}H_{39}N_3O_8$, and fusible at a temperature of from 143.5° to 144° C. It is not very soluble in water, but much more so in acidulated water, and soluble in all proportions in sulphide of carbon, absolute alcohol, chloroform, and benzine. Ether and the light essence of petroleum dissolve only traces of it. Myoctonine is a powerful poison, resembling curare in its action. The injection of $\frac{1}{1000}$ of a gramme produced distinct toxic symptoms in a cat, while one-tenth of a gramme caused death in twenty or thirty minutes. Lycoctonine and lycaconine, which are products of the decomposition of lycaconitine and of myoctonine, have a physiological action which recalls that of the primitive alkaloids, but less powerful.—*British Medical Journal*, Jan. 15, 1887.

TREATMENT OF CEREBRAL ANÆMIA.—DUJARDIN-BEAUMETZ advises the following regimen:

After each meal a teaspoonful of syrup of iodide of iron taken in seltzer water. On retiring, a teaspoonful of this mixture:

Potass. bromid.,				
Sodii bromid.,				
Ammonii bromid.	.	.	.	āā gr. xx.
				ʒ

Two sulphur baths should be taken weekly; when the temperature of the external air will permit, cold douches should be substituted for the sulphur baths, followed by

[illegible] of treating malignant pustule, for which the respective authors claim marked success, have lately been mentioned in Spanish journals. Dr. Avendaño, of Peru, makes a crucial incision, and applies the ordinary solution of ammonia to the cut surfaces with a brush, giving at the same time a mixture containing acetate of ammonia. Dr. Rivas, of Cartagena, applies to the affected part a paste composed of oil of turpentine and quinine. This latter is said to have been efficacious even in a case where it was applied by the patient himself without medical advice, after having seen the beneficial effects of the paste prescribed on a companion.—*British Medical Journal*, Jan. 15, 1887.

ANTI-NEURALGIC PILL.—The following is the formula

[illegible]

Quiniæ hydrobromat.	.	.	.	gr. jss.
Syrup. quinquinæ	.	.	.	q. s.

One pill may be taken every four hours, until five or six daily are taken; the frequency of the dose should be diminished as soon as the full effect is established.—

[illegible]

P. GRAY gave the following:

Mania, manifested by delusions of excitement, expansive ideas, exaggerations, self-consequence, incoherence, etc.

Melancholia, manifested by delusions of depressing character, painful ideas, and apprehensions.

Dementia, representing conditions of mental failure and feebleness of mental action.

All cases of insanity come under these three heads. Cases may be acute, subacute, chronic, periodic, paroxysmal, but they are mania, melancholia, or dementia. —*Med. Record.*

THE THERAPEUTICS OF WHOOPING-COUGH.—Last year MICHAEL, of Hamburg, originated a method of treatment by nasal insufflations of powders of pulv. resinæ benzoæ, chinin. sulph., and arg. nit. 1–10. Benzoin has an agreeable taste, no toxic effect, and is most serviceable. The author relates 250 cases in which this treatment was adopted. Of 100 carefully observed cases, 8 had no further attack after the first insufflation. In 3 of these there was a return and 5 were cured permanently. In 74 per cent. there was substantial benefit, no effect in 12 per cent., and increase of the cough in 14 per cent. 7 per cent. were cured in three days, 23 per cent. in less than twenty days; the rest occupied three to five weeks. In 20 cases there was improvement, with cessation of vomiting, epistaxis, and asphyxia. The best effects were observed in very new and very old cases. The duration of the treatment was fourteen days in 50 cases. The author's results are confirmed by the publications of Bachem, Guerder, Lublinski, Stoerk, and Ziem.—*Journal of Laryngology*, January, 1887.

AN APPLICATION IN BLENNORRHŒA.—UNNA applies the following, with a sound:

Ol. theobrom.	.	.	.	100 parts.
[illegible]				2 [illegible]
Argent. nitrat.	.	.	.	5 "
Balsam. Peruv.	.	.	.	2 "

Four or five catheterizations with a tin sound anointed with this mixture generally sufficed to cure chronic inflammations of the urethra; in some cases it was necessary to repeat the series of soundings several times, and in severe cases the injections of sulpho-phenate of zinc were also employed.—*Revue de Thérapeutique*, January 1, 1887.

PARTURITION AMONG THE SYPHILITIC.—COMBES, in 188 cases, found that parturition proceeded without fever in 141; in 35 cases fever occurred, but for reasons independent of the diathesis: in 12 cases the fever which occurred was distinctly referable to syphilis or its sequelæ. After a careful analysis of cases which had fever, the author distinguishes two as especially of specific origin.

Retention of the membranes occurred in 37 cases; traumatism, more or less severe, occurred in 47 cases; the placenta was found diseased in 25 cases; the cure or the amelioration of the specific lesions followed parturition in 38 cases.

Among children the results were as follows: With the mothers who had no fever living children were born in 65 cases; 17 were stillborn; 59 were macerated, and 17 died ten days after birth.

Among the women who had fever 23 living children were born; 2 were stillborn; 15 were macerated, and 3 died ten days after death.

In the 188 cases 113 children perished from syphilis, a mortality of 60.1 per cent.—*Annales de Dermatologie et de Syphiligraphie*, December 25, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM IN ADVANCE $5.00

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 12, 1887.

EXCISION OF THE KNEE.

IN the *British Medical Journal* for January 15, 1887, HERBERT ALLINGHAM describes a method of excising the knee-joint, which he believes to be new, but which really originated with Ollier, of Lyons. As it possesses decided advantages over the ordinary procedures, and as we do not doubt that it will prove to be new to the majority of our readers, no apology is needed for bringing it to their notice.

An incision, carried from two or three inches above the patella, over that bone, and down to the tubercle of the tibia, splits the quadriceps tendon into the synovial pouch above the joint, as well as the ligament of the patella, and the bone itself is sawed into two equal halves. These halves being held out of the way, the crucial ligaments are divided; and, the leg being flexed, the condyles of the femur are pushed forward on to the tibia, and a slice of bone removed. The leg being next completely flexed, the internal lateral ligament is carefully separated from the corresponding semilunar cartilage, through which the tibia can readily be carried forward, and a thin layer be removed with a knife or chisel. The entire synovial membrane is then carefully removed, and openings are made for drainage at the postero-lateral aspects of the joint. Should the patella be extensively diseased, it is shelled out of the quadriceps tendon; but if the cartilage be merely eroded, it is removed. If the patella is sound, the halves are sutured together with strong catgut, and the ligament of the patella and quadriceps tendon are dealt with in a similar manner. The skin is united separately, and antiseptic dressings applied.

It will be observed that the fascia lata, the lateral ligaments, and the prolongations of the vasti muscles to the tibia and fibula are not divided, through which the support to the joint, both during and after healing, is much greater than after other methods of operating. Dislocation of the tibia backward, and tilting of the femur forward are prevented, the quadriceps forming a strong antagonist to the hamstring muscles. Finally, progression is greatly improved, as the quadriceps is neither divided transversely nor shortened, as happens when the usual incisions are made.

These are manifest advantages, and certainly entitle the operation to a fair trial. It is certainly well adapted to cases of strumous synovitis, and cases in which the cartilage and bones are not extensively involved. Whether, as Allingham hopes, it will secure a movable joint, the future alone can determine.

ANÆSTHESIA IN LABOR DOES NOT CAUSE POST-PARTUM HEMORRHAGE

WE take pleasure in presenting to our readers a paper read by DR. FORDYCE BARKER, last week, at the annual meeting of the State Medical Society of New York. It is devoted to the discussion of the question as to the danger of post-partum hemorrhage being increased by the use of anæsthetics during labor. Possibly a better form of putting the question would be, Is there any liability to post-partum hemorrhage caused by anæsthesia in labor? But whatever the form of interrogatory, the subject considered is one of great practical importance, and we are glad that Dr. Barker has brought the rich treasures of his experience to its elucidation.

He gives unqualified preference to chloroform as the anæsthetic in obstetric practice, and presents some strong arguments for this selection; unquestionably it should be preferred to sulphuric ether, as he states, if there be albuminuria. But albuminurics are only a small class of parturient women, and we certainly believe that the vigor of uterine contractions is less frequently lessened if ether rather than chloroform be used. This, however, is not a material point in the discussion, and we pass from the choice of an anæsthetic to the important statement made by Dr. Barker, that uterine inertia, the fountain of post-partum bleeding, is often but another name for uterine exhaustion, "and this must certainly be much less likely to occur when the nerve-force and vital powers have been saved by the use of an anæsthetic."

While Dr. Barker admits that in some cases chloroform prolongs labor, he asserts, as the result of his experience, that the opposite effect occurs in the majority of women—that is, the labor is shortened by chloroform; and this happy result is a consequence not only of diminished resistance of the os uteri and the perineum, but also of the

lessened suffering, whether such suffering be the consequence of an intercurrent disease, or arise from extreme sensitiveness and fear.

In the further discussion of the subject he refers to women attended by him in labor, who in previous confinements suffered from uterine hemorrhage though taking no anæsthetic, while they escaped this accident following labors in which anæsthesia was employed. He adds to these cases others in which pregnancy was complicated by grave cardiac disease, and shows that in these, too, no accident followed the use of chloroform in labor, but, on the contrary, the results were most satisfactory.

The paper is one of very great value, and we trust will lead to the more frequent employment of anæsthetics in labor. Could the voice of those who have had the sufferings of childbirth, if not abolished, at least greatly mitigated by the judicious use of an anæsthetic, be heard and obeyed, no woman would endure the martyrdom of maternity without this relief. A distinguished foreign obstetrician once remarked to us that his wife—who had borne six children, and in all her labors used chloroform—never knew of his going to a case of childbirth without giving him the injunction to let the patient have chloroform.

Nevertheless, while advocating anæsthetics in childbirth, let us carefully draw the line between obstetric and surgical anæsthesia. There is truth in the remark made by Depaul, who rejected anæsthetics in physiological labor, that participation on the part of the patient is important; this applies especially to cases of pelvic presentation after the body has been delivered, and it is so important that the head should not linger or loiter in the pelvic cavity, for asphyxia is then inevitable, that it is then most unfortunate if, as a consequence of too deep anæsthesia, no voluntary and vigorous effort can be made by the woman, since the child soon perishes from delay in the delivery. This last fact suggests another question which has been sometimes mooted, Is there any danger of stillbirth caused by the mother's using an anæsthetic in labor? We hope Dr. Barker will at an early day find the leisure to prepare a paper in reply to this question. No man is better qualified to do the work than he; it would be equally useful with that now presented by him, and the conclusions drawn from his large experience would be most acceptable to the profession.

THE MEDICAL DEPARTMENTS OF THE ARMY AND NAVY.

THERE are at the present time no vacancies in the Medical Department of the Army, but at least three vacancies will occur during the present year by the retirement of officers who will have reached the limit of age (sixty-four years), and probably three or four more vacancies will be made by resignation, retirement for disability, or death. In the Medical Department of the Navy there are at present ten vacancies, with the prospect that additional ones will be created by retirement, etc.

For each Department an Examining Board will be convened to fill these vacancies, if possible. As the character and nature of the examinations are about the same for the two services, it would seem, from the number of vacancies in the Medical Department of the Navy, that that service is not as attractive to young physicians as is that of the Army, and the reasons for this are worth considering.

The pay of the Assistant Surgeon in the Navy, for the first five years after his appointment, is, per annum, when at sea, $1700; when on shore duty, $1400; when on leave, or waiting orders, $1000. After five years' service, his pay becomes, at sea, $1900; on shore duty, $1600; and when waiting orders, $1200. There seems to be no good reason for the difference in pay for sea and shore duty.

The pay of the Assistant Surgeon in the Army, for the first five years after his appointment, is, per annum, $1600, and, after five years, $2200. For the first ten years of service, or thereabouts, the pay of the Army medical officer is somewhat greater than that of the Navy medical officer. But promotion is more rapid in the Navy than in the Army, owing to the fact that the Navy has more officers in the higher grades. Thus, of 180 medical officers in the Navy, there are 15 with the rank of Colonel, and 15 with the rank of Lieutenant-Colonel; while, of 192 medical officers in the Army, there are 5 Colonels and 10 Lieutenant-Colonels. The result of this is that while in the Army it requires about twenty years' service to reach the rank of Major and full Surgeon, in the Navy it requires a little less than fifteen years to attain this grade. Taking it altogether, there is very little difference in the pecuniary emoluments of the two services.

The important point in which the Naval Medical Service seems to be less satisfactory than that of the Army is in relation to absolute rank, and, more especially to the position during the early years of service. The Junior Assistant Surgeon in the Navy is not on an equality with commissioned officers. He has no place in the ward-room, and no room to himself. He has a bunk in the steerage, and messes with the midshipmen and the clerks of the Captain and Paymaster, having practically no privacy, and very inferior opportunities for study. The Junior Assistant Surgeon in the Army has his own quarters, his rank is that of first lieutenant, and his position

is in every way equal to that of other officers of his own rank.

It is this fact which makes the medical service of the Army more popular than that of the Navy, and it is a fact which the Navy Department will do well to consider carefully. It probably requires Congressional legislation to remedy the difficulty. Twenty-five years ago the young Assistant Surgeon in the Navy was a ward-room officer. But under the Act of March 3, 1871, fixing the relative rank of staff officers in the Navy, it is directed that "assistant surgeons shall have the relative rank of master or ensign," that "no staff officer shall, in virtue of his relative rank, have any additional right to quarters," and that "ensigns shall be steerage officers, unless assigned to duty as watch and division officers." There is room for doubt as to the proper interpretation of this law, and until this doubt is removed it is not probable that the Junior Assistant Surgeons in the Navy will receive the consideration to which their education and age justly entitle them. They obtain their education at their own expense, and not at that of the Government as the line officers do, and they are entitled to associate with any officers on board ship. Until this matter is remedied, the Army medical service will be preferred by the young, well-educated physician; and properly so, for the man who can pass either the Army or the Navy Medical Board is, so far as intellect and education are concerned, fully qualified to associate on equal terms with any officers in either of the Government services.

PROTECTIVE INOCULATION AGAINST RABIES.

THERE has been a great deal of scepticism about the method of protective inoculation against rabies introduced by Pasteur, and in the absence of certain essential details it has seemed reasonable to doubt, even in the face of his remarkable results, whether he was dealing with true hydrophobic virus. Nowhere have the criticisms been more pungent or unsparing than in this country, though they have usually lacked the weight which we accord to judgments based on observation, and to opinions supported by experiments.

Last Monday, DR. ERNST, of Harvard University, presented to the Academy of Surgery of Philadelphia the results of his investigations upon Pasteur's method, and the members of the Academy and the profession had the privilege and pleasure of listening to a contribution worthy of the subject. Dr. Ernst obtained his material direct from Pasteur's laboratory, and has carried out in full detail the method there employed. His conclusions confirm in almost every point those of Pasteur, viz., the existence of a specific virus in the animals experimented with, the possibility of attenuating this virus, and the protection afforded by inoculations. Dr. Ernst began the work as a sceptic, and was quite uninfluenced by personal considerations, as he had not studied in Pasteur's laboratory.

The only doubt which exists is as to the nature of the virus with which Pasteur has been working so long. Is it the same as true street rabies? Many of the opponents of the method maintain that this laboratory disease is different from the ordinary rabies, and we have wondered that inoculations have not been made from recent and undoubted cases in the dog. This has, however, been recently done by Prof. Frisch, of Vienna, who has established the identity of the virus with that with which Pasteur works.

DECOCTION OF COTTON-ROOT AS A UTERINE HÆMOSTATIC.

HAVING repeatedly tried cotton-root, in the form of the fluid extract, as a uterine hæmostatic without marked beneficial results, our conclusion was that the remedy was without any great value. The experience of DR. GARRIGUES, as made known in the *Quarterly Bulletin* of the Clinical Society of the New York Post-Graduate Medical School and Hospital, proves that the drug given in the form of decoction produces markedly beneficial results. The following are his directions for preparing and administering it: Three heaping teaspoonfuls of the powdered root are boiled in a pint of water for fifteen minutes; after cooling the preparation is strained: one-third of the decoction is taken in the forenoon, another in the afternoon, and the last at bedtime.

Dr. Garrigues has used the remedy in 139 patients, and in the great majority of cases with more or less decided benefit. He has found that it checks the bleeding from uterine fibroids, and also lessens the associated pain; while in sarcoma and carcinoma it limits, or altogether suspends, for a time hemorrhage. He insists that the remedy should be used in the form of a freshly made decoction, and states that it fails to produce any benefit in about one in ten cases, which is certainly not an unsatisfactory showing.

The attention of the profession will doubtless be directed anew to the use of this remedy by the important and apparently conclusive results obtained by Dr. Garrigues, who, as is well known, is one of our most capable and conscientious observers.

THE new Japanese Pharmacopœia, which has been compiled under the supervision of the Sanitary Bureau of the Home Department, has just been issued, and, by direction of the Home Minister, it comes into use from the first of July next. We understand that Dr. Eykman, who was one of the Commission which framed the Pharmacopœia, is now engaged upon a work similar in scope to our

National Dispensatory, which is to accompany the official Pharmacopœia, and is to be issued before July, 1887.

The new Pharmacopœia is based on the American, German, and British, and contains 475 articles. The official text is Japanese, but the whole work is also to be published in Latin. The metric system forms the basis of measurements, but the proportions are given in parts by weight.

The New York State Medical Society held its annual meeting last week at Albany. The following were elected officers for the ensuing year: *President*, A. L. Loomis, of New York; *Vice-President*, A. M. Phelps, of Chateaugay; *Secretary*, William Manlius Smith, of Syracuse; *Treasurer*, Charles H. Porter, of Albany; *Censors*—Southern District, J. S. Warren, of New York; M. B. Chase, of Brooklyn; and W. H. Helm, of Westchester. Eastern District, J. Lewi, of Albany; Thompson Burton, of Montgomery County; and L. McLean, of Troy. Middle District, J. G. Orton, of Binghamton; Robert Frazier, of Oneida County; and I. N. Goff, of Madison County. Western District, Theodore Dimon, of Cayuga County; M. S. Kittinger, of Niagara County; and David Little, of Monroe County. College of Medicine, Syracuse University, Harvey Jewett, of Ontario County.

The profession will regret to learn of the death, at Charleston, S. C., on February 3d, of Dr. J. F. M. Geddings, aged fifty-eight years. He was the eldest son of Prof. Eli Giddings, who for many years was Professor of the Practice of Medicine in the Medical College of the State of South Carolina, and the most conspicuous physician in that State. He inherited much of his father's ability, and succeeded to a good share of his business. He was educated in Charleston, and also in Berlin and Paris. He exhibited during his career a decided partiality to German methods of research and views of pathology, and was regarded as well versed in the literature of the profession, and as proficient in methods of diagnosis. His general scientific and literary attainments were also of a high order.

Dr. Geddings had been almost a life-long sufferer, in his youth from hip-disease, following scarlet fever, and in advanced age from paroxysms of angina pectoris. To a certain extent his usefulness was thus impaired, but he continued to the end a general practitioner, highly valued for his knowledge, his skill, and his devotion to his profession. He had a kind heart, and he was as true as steel to those who trusted him, and was never forgetful of professional responsibility or ethics. His untimely end he had foreseen, and to some extent predicted. Seized with symptoms of pulmonary congestion, or pneumonia, he still struggled on in the discharge of his professional duties up to the day preceding his death. Upon taking to his bed, from the direst necessity, it was soon discovered that a much hypertrophied heart so complicated the situation that there was but little hope of recovery. In less than twenty-four hours his noble heart had ceased to beat.

The danger of the telephone as a conveyer of infectious diseases has attracted the attention of Dr. A. P. Astvatzatüroff, of Tiflis, and he has called the attention of the Caucasian Medical Society to the risk of infection from the promiscuous use of the mouth-pieces of public telephones. To prevent this accident, he gravely recommends that some disinfectant fluid should be kept at every telephone station, and the speaker should, first of all, dip the mouth piece into the fluid, and then wipe it with a clean towel.

A cablegram announces the death of Professor Schröder, of Berlin, gynecologist and obstetrician. As the author of the German text-book on obstetrics most widely quoted, and of a manual of gynecology extensively read, he is well known here; while a long and honorable career as an operator and instructor has raised him to a most eminent position in Berlin. His clinic, in its excellent building, is one of the most completely equipped in Germany, and his instruction has been eagerly sought by students from all parts of the world. Professor Schröder was about fifty years of age.

By the vital statistics in Michigan it is found that smallpox has been comparatively epidemic every five years. Thus, in 1872 there were 302 deaths reported in Michigan from the disease; in 1877 there were 102, and in 1882 there were 100. This is the last year of one of these five-year periods, and, according to past experiences, it is thought that we may expect the disease this year. Smallpox is present in New York, Ohio, and Wisconsin, and if immigration is large this year, the danger from it may be increased. The moral is, that this is a good year for vaccination against smallpox.

The Executive Committee of the International Congress of Hygiene and Demography, which will meet from September 26th to October 1st in Vienna, is pushing forward preparations. The participation of a number of men, well informed upon the topics for discussion, has been already secured. In the two general sessions which will be held, papers and oral statements only will be received; discussions will be referred to appropriate sections of the Congress. Especial stress will be laid upon the scientific value of the meeting, and the element of festivity will occupy only an incidental relationship.

A cablegram from London states that the Right Hon. C. T. Ritchie, President of the Local Government Board, announced in the House of Commons last Tuesday the appointment of a committee to consider and report upon the advisability of establishing a hospital for the treatment of persons afflicted with hydrophobia; the institution to be conducted upon the principles established by M. Pasteur in Paris.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 12, 1887.

The President, Charles McBurney, M.D., in the Chair.

Dr. Lange presented two patients showing the result of

INGUINAL COLOTOMY.

The operation he described as follows: It is a well-known fact that in the operation of colotomy, inguinal as well as lumbar, in which merely a lateral opening in the gut has been made, the contents of the latter will, as a rule, escape, to some extent, into the intestine below the wound, and being forced upward by antiperistaltic action, will prolong and render difficult the process of defecation. He confessed that in nearly all of his cases of colotomy, which were performed according to the above method, the result in regard to this point had been unsatisfactory until he adopted Madelung's plan of cutting across the entire gut, closing the end of the lower portion, and stitching the upper end into the abdominal wound. The result was perfect, so far as concerned defecation; the patient passed feces once or twice a day in a short period of time, and was free from all annoyance during the rest of the day.

From reading a discussion that took place at the Paris "Société de Chirurgie," his attention was called to the possibility of danger eventually arising from retention in the closed portion of gut above the point of stricture; and he, therefore, adopted in his last three cases Verneuil's plan of forming a spur, and thus securing the complete evacuation of the feces through the artificial anus, while at the same time the interior of the lower portion of the gut remains accessible.

The technique of the inguinal operation is as follows: Under strict antiseptic precautions an incision is made parallel with Poupart's ligament, and about three centimetres above its outer third. The peritoneum is opened to the extent of not more than three or four centimetres, a loop of the colon, in the region of the sigmoid flexure, is brought into the wound, and a needle armed with a coarse catgut ligature is passed under the gut at the point of attachment of the mesentery; the ligature is not tied, but serves merely as a handle. A spur is then formed by passing through a part of the intestinal wall on both sides of the mesentery a fine needle threaded with iodoform catgut, the line of stitches being about equal to the thickness of the abdominal wall, or perhaps a little longer. Then by similar sutures the opposite parietal and visceral peritoneal surfaces are brought in contact, so that the peritoneal cavity is entirely shut off from the wound, and the loop of intestine so far as its peritoneal surface had been approximated by stitches, will be secured above the level of the parietal peritoneum. The gut is then opened by an incision, extending in a transverse direction toward the attachment of the mesentery, the edges being united to the integument by a few sutures of silkworm gut. Some iodoform gauze is introduced into the properitoneal space at each angle of the wound: this promotes good drainage during the first twenty-four hours. The wound is dressed with vaseline and iodoform powder.

He had performed this operation three times at the German Hospital, within a period of fourteen days. Two of the patients had inoperable cancer of the rectum, the third an extensive syphilitic stricture. Recovery followed rapidly in each instance, without any unfavorable symptom, and the final result is so satisfactory that he felt justified in recommending this method.

He exhibited two of the patients. In one of them there was observed a slight prolapse of the mucous membrane, which the patient attributed to the fact that she did not that day adjust properly the elastic belt which retains a pad of cotton against the opening. These patients, as well as the third, who could not be present, discharge their feces through the artificial anus. Defecation occurs once or twice daily, and occupies only a few minutes. The lower portion of the gut can easily be washed out, by introducing a thick rubber tube into the rectum, seating the patient upon a chamber, and injecting fluid through the artifical anus. This procedure is an important one, especially in the case of syphilitic stricture, whose history is briefly as follows:

She is a married lady, about thirty-six years of age, who contracted syphilis from her first husband. Dr. Lange treated her for about six years for stricture of the rectum, accompanied with extensive and obstinate ulceration; colotomy was proposed long ago, but she would not consent to it. In October, 1886, a severe pelvic peritonitis developed, apparently due to extension of the ulceration to the intestine above the seat of stricture; there was considerable exudation, and an abscess formed that was evacuated through an incision made on the right side above Poupart's ligament. It was necessary to separate adherent coils of intestine in order to reach a large collection of extremely fetid pus which filled the entire true pelvis. A counter-opening was made in the vaginal fornix. Within several weeks the patient rallied sufficiently to admit of the performance of inguinal colotomy. In spite of her miserable condition, recovery was perfect, and her strength and state of nutrition have been greatly improved. There is still a discharge of pus and blood from the rectum, but there is much less than before.

Dr. Sands remarked that, three days before, he had been summoned to the country to perform colotomy upon a gentleman suffering with cancer of the rectum. He made the usual lumbar incision, and had no difficulty in recognizing the various layers of tissue until the peritoneum was reached. Thinking that he had identified the latter, he proceeded to puncture it cautiously, when a clear serous fluid escaped. Seizing what he supposed was the colon, he proceeded to stitch it into the wound, intending to leave it for twenty-four hours before incising it, in order that the parietal and visceral serous surfaces might become adherent. The

needle that he employed made such a large puncture, that he judged it expedient to open the gut at once, which was accomplished successfully. This case was the only one in which he had failed to open the colon behind the peritoneum; the failure was undoubtedly due to the complete investment of the colon by the serous membrane. The late Dr. Mason encountered two similar cases, and wrote a paper in which he called attention to the fact that the colon sometimes took an abnormal course. In one instance the operation of colotomy was being performed at Charity Hospital, and a portion of the gut was exposed, which, in the opinion of several surgeons who were present, was large intestine. At the autopsy it was found that a loop of small intestine had been fastened in the wound. It is better, he thought, to seize and secure the small intestine if it appear in the wound, rather than to spend too much time in searching for the colon; danger is best avoided by suturing the gut to the wound, and waiting for adhesion to take place before opening it. The patient operated on by Dr. Sands made a prompt recovery, and was convalescent when heard from ten days afterward.

Dr. Gerster said that, after witnessing one of Dr. Lange's operations, he was so much pleased with the idea that he adopted it in the case of two patients, upon whom he performed inguinal colotomy the same afternoon. He preferred the inguinal to the lumbar incision, not only because it is easier to reach the intestine by the former method, but because patients find it much easier to cleanse themselves when the artificial anus is in front. There is no doubt that it is often a difficult matter to find the colon in lumbar colotomy, especially when it is not blown up, so that the surgeon is often obliged to content himself with the next best thing, a loop of small intestine; moreover, it is necessary to divide a number of thick strata before reaching the cavity. In the inguinal operation, on the contrary, the abdominal wall is much thinner, it is easier to recognize the gut, and the subsequent introduction of sutures is less difficult. In one of his cases feces escaped into the lower portion of the bowels for two or three months because the spur that had been formed was made too short through the subsequent contraction of the parts; however, this was corrected. The suture was very much facilitated by seizing the parietal peritoneum on each side with artery forceps, and drawing it well out, when it was quite easy to unite the two serous membranes in extensive contact.

Dr. Sands remarked that a German writer has laid much stress upon the importance of uniting the parietal and visceral peritoneum before opening the gut; he first stitched the parietal peritoneum to the skin, and then the former to the serous covering of the intestine, thereby securing perfect adhesion of the latter to the edge of the wound. His own experience had been different from that of Dr. Gerster. One of the three patients, upon whom he had performed lumbar colotomy, and who was under observation for six months, had been much annoyed by the escape of feces from the opening. They seemed to be retained better after lumbar colotomy.

Dr. Gerster said that he had been misunderstood; he only referred to the greater ease with which the patient can cleanse himself when the artificial anus is situated anteriorly. The escape of feces can often be prevented by making the incision in the abdominal wall only as long as is absolutely necessary. If it is too long, prolapse is apt to occur. In one of his cases, where the intestine was small, and its wall and the abdominal incision too ample, there was afterward some prolapse; in the other, a small incision was made, and there was no prolapse, a perfect funnel-shaped opening resulting. The final result of the operation, regarding the shape of the artificial anus, depends, to a great extent, on the local peculiarities of the abdominal walls and gut of different individuals.

Dr. Lange said that in his cases the contents of the bowel were, as a rule, discharged only once or twice after the operation. When the intestine is merely opened by a lateral incision, the fecal matter is apt to pass by the opening into the lower portion of the colon, and to be regurgitated in consequence of the antiperistaltic action, thus causing the patient great annoyance.

Dr. Lange prefaced his description of

A NEW RADICAL OPERATION FOR HEMORRHOIDS,

by stating that in mild cases he had obtained good results by injecting equal parts of glycerine and pure carbolic acid. In severe cases, complicated with prolapse of the mucous membrane, he had adopted a method of operation that was to be commended not only on account of its facility and the completeness of the cure, but because of the fact that it is not followed by suppuration and necrosis of the tissues. It consists in excising the entire affected portion of the mucous membrane, and in suturing the edge of the remaining part to the integument. The essential advantages are the perfectly aseptic character of the process, and the small loss of blood.

He described the operation briefly as follows: After the patient has been duly prepared by proper attention to diet, and the thorough evacuation of the bowels, a sponge is pushed high up into the rectum, and the lower part of the gut is thoroughly irrigated with a weak solution of corrosive sublimate, followed by one of boro-salicylic acid. The patient is thoroughly anæsthetized, so as to avoid straining and consequent venous congestion. The field of operation is constantly irrigated with an ice-cold boro-salicylic solution. An incision is carried around the anal orifice at the line of junction between the skin and mucous membrane, the parts being put on the stretch by making traction with tenacula. If the skin is flabby and in excess, a portion of it may be included within the incision; the latter is carried downward until it reaches the fibres of the external sphincter, the distended hemorrhoids being easily avoided. The mucous membrane is easily separated from the sphincter as far upward as may be deemed necessary. In this way the entire degenerated portion is isolated and, so far as the arterial blood supply is concerned, remains connected with the healthy tissue only by the vessels that supply it. So far but few bleeding points require to be secured. If now the entire diseased part should be excised, there would undoubtedly be a considerable loss of blood, as occurred in his first case; the mucous membrane would retract as it was divided, and the operation would be long and embarrassing. He therefore inserts a number of buried sutures of iodoform-catgut close to each other, between the base of the external flap and that of the separated mucous membrane; these do not

include any of the fibres of the sphincter, neither do they penetrate into the rectum. He lays particular stress upon the avoidance of the sphincter, since he has observed in several cases that the patient suffers from severe tenesmus if the stitches penetrate the sphincter. The sutures may be either continuous or interrupted; they secure nearly all the vessels supplying the hemorrhoidal portion. The mucous membrane is excised in parts, at a point from one-half to one centimetre above this line of sutures, and the cut edges are approximated by sutures of silkworm gut.

In several instances he had passed deep stitches which included the entire sphincter, in order to diminish the tension, but he thinks that these can be dispensed with.

From the beginning of the third day following the operation, the patient is allowed to have a passage daily, and is kept on liquid diet for a week, at the end of which time the sutures may be removed; a few days later he may be allowed to get up, and at the beginning of the third week he will, in his experience, be able to attend to his business.

Much of the success of this operation depends upon the technique. He can testify from his own experience in about a dozen cases, that the rapidity and completeness of the healing process, the comfort of the patient, and, in short, the neatness of the entire procedure, have induced him to prefer it, in suitable cases, to other methods (Allingham's, Langenbeck's, etc.). Strict antisepsis and the avoidance of hemorrhage, in the manner described, he regards as indispensable to success. (A patient was presented upon whom the operation had been performed three weeks before.)

Dr. Lange presented a patient upon whom he had performed

COMPLETE EXCISION OF FISTULA IN ANO.

Year before last he proposed, at a meeting of this Society, the advisability of treating fistula by excision of the entire fistulous tract, the raw surface being brought together with sutures, with the view of securing healing by first intention. He described a certain method, but his experience at that time was derived from a few operations, the results of which were only partly successful, though encouraging. The first operation was performed two years ago upon a lady who had a deep-seated fistula, the internal opening of which was situated two or three inches above the sphincter. She was perfectly cured in two weeks. Since then he has had about a dozen cases in which the extent of the lesion and the gravity of the operation varied, the results being as follows: In four cases primary union occurred without suppuration, in three a similar result was obtained with but slight suppuration; in four the wound healed by granulation, in a shorter time than it would have done after one of the old operations. In one instance I did not sew up the wound at all on account of inflammatory infiltration of the edges; in another, that of a gentleman whom he had treated during the acute stages of a very extensive gangrenous periproctitis, there was so much cicatricial tissue that he did not venture to excise it all for fear of removing so much of the muscle that incontinence might result, this patient has still an internal fistula, which does not cause any inconvenience, except a slight discharge.

His technique has been essentially the same as that described at a former meeting, viz., excision of the entire fistulous tract, together with all the lateral sinuses, such as not infrequently exist in the cellulo-adipose tissue above the sphincters, and union of the deep tissues by means of buried sutures of iodoform catgut, as well as accurate adaptation of the edges of the mucous membrane. Several sutures include the entire field of operation, in order to relieve the tension of the parts. The field of operation is constantly irrigated with boro-salicylic solution. The edges of the integument he prefers to unite by only a few sutures, in order to allow drainage of the first secretion. Opium is administered during the first two days. After the second day the bowels are moved easily with injections, a sitz bath being used after defecation.

He has performed this operation only once in a case of fistula of tuberculous origin, the result being perfect. There was a large shallow sinus, which did not communicate with the rectum—a condition which, in his experience, is not infrequent in tuberculous fistulæ. He is skeptical regarding the existence of so-called incomplete external fistulæ in other cases, having always succeeded in finding the internal opening, except once, in a dermoid fistula. Neither does he accept the general opinion that muscular contraction prevents a fistula from healing, as it is very probable that the entrance of obnoxious matter into the sinus causes repeated attacks of inflammation, and accounts for the chronic nature of the affection. In the last patient upon whom he operated a few days ago, he did not find an internal opening, its site being occupied by a slight elevation, covered by a thin cicatricial tissue. This was probably only transient cicatrization.

In the *Medical Record* of June, 1886, Dr. Stephen Smith published a paper on this subject, in which he states that in 1879 he conceived the idea of treating fistula in this manner, after reading in Dr. Emmet's book a description of that gentleman's plastic operation upon the perineum. At that time Dr. Smith excised the granulating surface of a fistula that had been operated upon unsuccessfully six months before; consequently, that operation was scarcely applied to a fistula proper. He does not state just when he adopted the method described by him; but, if it was immediately after the operation above mentioned, he was probably the first surgeon to practise it. Dr. Lange took the liberty of claiming priority in his description of the details of the operation, and especially the use of antiseptic precautions, which differs in no essential feature from that given by him.

The patient presented had a very extensive V-shaped sinus, one branch of which ran high up, parallel with the rectum, the external opening being situated about four inches to the right of the anus, while the internal was above the external sphincter. After the operation an enormous cavity was left, into which the fist might have been inserted. In this case the internal wound was only partially closed, and was drained with iodoform gauze. The operation lasted several hours, and, in fact, could not be completed on account of the fading light. Recovery was interrupted by the occurrence of retention after transient apparent healing. She now had perfect control of her bowels, and does not suffer from diarrhœa. The sphincter in the last case is not perfectly sound.

DR. HALL asked how soon the bowels were moved after the operation.

DR. LANGE replied that at first he allowed them to remain constipated for from ten to fourteen days, but now he orders an enema of oil on the morning of the second day and a laxative the same evening, so as to insure a soft stool on the third day.

DR. SANDS did not see what advantages were claimed for the new operation for hemorrhoids, but he presumed that its purpose was to avoid the hemorrhage which was so much dreaded by the older surgeons. He thought that most of the members of the Society were partial to the use of the ligature, especially in cases in which there was much prolapse; a certain amount of inflammation took place around the ligature which favored adhesion of the intestine to the adjacent parts, thereby guarding against further protrusion. The old operation of Allingham is perfectly satisfactory, and the surgeon, after performing it, can leave his patient, feeling that there is no danger of hemorrhage. The speaker did not attempt to strip off the mass at all, but simply incised the skin around the base of the pile sufficiently to allow the complete burying of the ligature and, the mucous membrane being drawn down as far as possible, the risk of subsequent stricture was avoided. It would require a good deal of argument to induce him to abandon the old operation.

He had practised the method of complete excision of anal fistula in four cases, only one operation being successful. Only small, straight fistulæ can be excised with the expectation of their healing by first intention; in complicated fistulæ it is necessary to remove a good deal of tissue, which, in the vicinity of the anus, is particularly undesirable in view of the subsequent cicatricial contraction. The operation is certainly not adapted to all cases. Fistulæ can be cured by simply scraping out the tract.

DR. LANGE admitted that the method is not applicable to every case, but it can be employed successfully even in cases of tortuous sinuses extending high up the rectum; moreover, the result is equally good when the wound is not closed, but is allowed to heal by granulation. It is important, however, to bring the edges of the mucous membrane in apposition, as healing is retarded by contact with fecal matter.

THE PRESIDENT presented a patient showing the results of

EXCISION OF THE ANKLE-JOINT,

whose history was as follows:

Annie Duval, aged eighteen, colored, was admitted to St. Luke's Hospital March 11, 1885. About a year before her admission she had sprained her ankle severely, and suppurative synovitis followed; the pus had been evacuated by incisions. Her family history was phthisical. On admission, her ankle was swollen and tender, and evidently contained fluid; a sinus behind the internal malleolus communicated with the interior of the joint. On the 31st of March he excised the joint, making a curved incision behind each malleolus, and removing the lower end of the tibia and fibula by a horizontal section, as well as the entire upper surface of the astragalus by a parallel cut. The limb was put up in a permanent dressing covered with plaster of Paris, and so retained till April 28th. The wound healed perfectly in eight weeks, since which time the patient has walked with ease, limping only slightly. Slight subcutaneous suppuration occurred recently, which healed at once after scraping. Motion is now quite free, and the joint is strong. The shortening amounts to seven-eighths of an inch.

THE PRESIDENT also showed a

CASE OF ANEURISM OF THE INNOMINATE ARTERY TREATED BY LIGATURE OF THE CAROTID AND SUBCLAVIAN.

Martin Cavanagh, an Irishman, aged thirty-five, was admitted to St. Luke's Hospital March 9, 1886. He was probably syphilitic. Two weeks previously he had noticed a tumor on the right side of the neck, just above the inner end of the clavicle; a week later he became hoarse, and at the time of his admission he could speak only in a whisper. The tumor was considered to be an aneurism of the innominate artery, involving probably the commencement of the carotid and subclavian arteries. Pulsation was very marked, and was readily felt to affect the upper end of the sternum, the inner end of the clavicle, and the first two intercostal spaces. On April 16th it was found that the tumor had grown decidedly, and then measured three and three-quarter inches transversely, and extended to a point a little above the cricoid cartilage, displacing the trachea to the left. He considered the hoarseness to be due to tension of the right recurrent laryngeal nerve. The patient was kept in bed, and received ten grains of iodide of potassium three times a day until April 16th, during which interval the tumor became somewhat larger. He operated on April 20th, applying a catgut ligature to the carotid in its upper portion, and another to the third part of the subclavian. Pulsation almost entirely ceased in the tumor. The wounds healed very rapidly. On May 26th, the patient was put upon strict diet, according to Tufnell's plan, and was kept in bed until July 28th, since which time he has been about the ward, and has taken ordinary diet. The tumor has steadily diminished in size, and is now considerably less than one-fourth of its original size, the wall of the sac being thick and firm. The voice is only slightly hoarse.

TORONTO MEDICAL SOCIETY.

Stated Meeting, January 21st, 1887.

THE PRESIDENT, DR. MCPHEDRAN, IN THE CHAIR.

DR. TEMPLE showed

THE UTERINE APPENDAGES

removed on account of purulent inflammation of both Fallopian tubes. The patient, æt. thirty-three, had been married eleven years, was never pregnant, began to suffer one year after marriage. During the last year was almost constantly confined to bed, as any exertion caused severe pain in the pelvis lasting several days, probably due to attacks of circumscribed peritonitis. She was a thin woman, and the abdomen was enlarged equal to the fifth month of pregnancy. On vaginal examination the uterus was found pushed forward and upward so that the cervix could be felt with difficulty behind the pubic symphysis. The Douglas cul-de-sac was filled with a fluctuating mass. The right tube could be ac-

curately mapped out by bimanual palpation; the left could not be so well outlined. On opening the abdomen the mass presented the appearance of a fibro-cyst. The structures were greatly matted, the adhesions being separated with difficulty. The right tube burst during separation and about eight ounces of pus escaped into the pelvic cavity. The right ovary was removed; the left could not be found; it had probably become absorbed from pressure. The patient made satisfactory progress, the temperature not exceeding 101° F.; usually varying from 99° to 100° F.

Dr. Ross exhibited a

PLACENTA FROM A CASE OF TWIN PREGNANCY,

in which the cords, which were attached to the placenta very close together, were inextricably knotted. Death of both fœtuses had occurred some days before birth.

Dr. McPhedran exhibited the stomach, lung, and œsophagus from a case of

GASTROSTOMY FOR MALIGNANT STRICTURE OF THE ŒSOPHAGUS,

with the following history:

Eliza S., aged forty-one, unmarried, first consulted him in April, 1886. Her digestion had always been weak but otherwise her history was good, as was also her family history. At Christmas, 1885, she began to experience pain behind the lower part of the sternum and in the mid-dorsal region, with difficulty in swallowing. The pain was not increased by food. By March she was unable to swallow solids, and much of the liquid was returned as soon as swallowed. Mouthfuls of clear mucus were frequently ejected from the œsophagus without nausea or distinct act of vomiting. A sound gently introduced, was arrested eleven inches from the upper dental arch, showing a stricture about three inches from the cardiac orifice of the stomach. A No. 10 catheter, English scale, passed fairly easily but caused some pain; after a few days a No. 12 passed, but beyond that the stricture could not be dilated. A catheter with a funnel attached was introduced four times daily for the purpose of administering nourishment and for a short time she improved in appearance. The stricture gradually contracted, so that by June 1st, only a No. 8 catheter could be used, and even it caused so much pain that it was evident she could not continue to take nourishment much longer in this way. Rectal alimentation was resorted to, but each enema induced such severe colic that they could not be continued. As she suffered much from hunger and thirst, especially the latter, gastrostomy was proposed, the risks and disadvantages being fully explained to her.

After some hesitation she decided to submit to the operation and the first stage was done on the 11th of June. An oblique incision, three inches long, was made three-fourths of an inch below and parallel to the eighth and ninth costal cartilages till the sheath of the rectus was opened, when the direction of the incision was changed to that of the fibres of that muscle, so as to secure the benefit of any sphincter action it might subsequently exercise. On opening the peritoneum, the margins of the liver, gastrohepatic omentum, and stomach were exposed, the latter contracted and overlapped by the omentum, which was traced up to the under surface of the liver in order to make certain of the stomach. The stomach was then drawn downward and to the right, a fold of it drawn through the abdominal opening and transfixed by two harelip pins about one-half inch apart and lying across the line of the skin incision. The pins transfixed only the serous and muscular coats. Silk sutures were now introduced so as to bring together the peritoneal as well as the superficial parts of the wound closely around the protruding portion of stomach; but no sutures were introduced into the stomach, it being held firmly in place by the pins. The wound was freely dusted with iodoform, over which dry gauze and salicylated wool were placed and held in position by a broad flannel bandange.

She reacted satisfactorily after the operation, ether being used. The dressing was not changed till the fifth day, when union was found to have taken place by first intention. The gauze covering the protruding portion of stomach was so firmly bound down by plastic effusion that its separation caused a little breaking down of the union between the stomach and the superficial part of the wound, which took a few days to unite.

Temperature and pulse were normal throughout, and the only discomfort complained of was a little soreness, for a few days, at the wound on moving the body. She was nourished by enemata for three days; after which some food was given by the stomach tube which was, at first, more easily introduced than before operation.

The stomach was opened on the 21st of June, the tenth day after the preliminary operation. A narrow blade was introduced between the pins and then a No. 6 catheter passed into the stomach, a large syringe attached to it, and three ounces of milk slowly injected. The catheter was left in, a compress being placed around it. The opening of the stomach caused no pain or discomfort beyond a little nausea, no anæsthetic was therefore used. The size of catheter was gradually increased until a soft rubber tube, equal to No. 18, English scale, was introduced. From the first there was some trouble from leakage around the tube with some excoriation about the opening. With this exception she experienced great relief through the operation. She gained strength, and was able to walk and drive out with comfort—the pain in the chest became much less and was often absent for days. Her condition was very good from July to October, her chief complaint being of the leakage around the tube and the profuse ejection of mucus from the œsophagus, and occasional hemorrhages. Toward the end of November she began to fail rapidly, though still taking food freely. The oozing increased as her strength failed. During December she was confined to bed, cough developed and increased, with increasing dyspnœa. There were, at times, free hemorrhages. Her weakness increased till she died, on the 28th of December, six months and eighteen days after the operation was performed.

On post-mortem examination the seat of operation showed firm union between the wall of the stomach and the abdominal wall, the margin of the liver being also adherent, the fistulous opening was about one inch from the pylorus. The stomach was much dilated, and the walls thinned as compared with its condition at the time of operation; it now extended two inches below the fistulous opening. The upper part of the œsophagus was dilated; the lower five inches were converted into a sloughy cavity filled with offensive grumous material.

The growth was adherent to the bronchi, aorta, and spine; the inner surface of the aorta showed signs of invasion. The lungs showed no signs of deposit, but their back parts were in an advanced state of hypostatic pneumonia, which was doubtless the immediate cause of death.

The objects aimed at by operating in this case were fully attained, viz., first, and chiefly, the relief of suffering from hunger and thirst; and secondarily, the prolonging of life. The oozing from the fistula was disappointing; it could probably have been avoided by introducing the tube each time food was given instead of retaining it permanently in the fistula. For the purpose of giving food an ordinary enema syringe could be used, a funnel being attached to one end and a small tube to the other after the method recommended by Bryant.[1]

Gastrostomy, at best, is, unfortunately, only palliative in malignant disease. Nevertheless, as the dangers attending it, as in abdominal sections generally, are now comparatively slight, almost *nil*, in fact, since its division into two stages, it is one worthy of careful consideration in all cases of œsophageal stenosis. During the last few years all the deaths from it have probably been from prostration on account of the operation having been too long postponed. Of thirteen cases operated on by Dr. Kun, of Moscow, ten recovered and three died, one from perforation of the left bronchus on the second day, another from hemorrhage on the eighth day, and the third from prostration on the twelfth day.[2] Suturing the transverse colon instead of the stomach is a possible source of danger, and has occurred to some of the most eminent surgeons.

In this case the stomach was secured after the method practised by Boyce Barrow, of the West London Hospital.[3] This method is as efficient as, and more expeditious than by the double circle of sutures recommended by Howse, to whom is due the credit of having rendered the operation safe by dividing it into two stages. Barrow's directions were departed from in that only the serous and muscular coats were transfixed by the pins; this method, while rendering the subsequent opening of the stomach more difficult on account of the mucous membrane receding so far from the surface, probably secures greater certainty of asepticism in the wound, as septic matter may find its way along the pins from the stomach if these pierce the mucous membrane.

The sutures for closing the wound might, with advantage, be passed before transfixing the stomach with the pins, as the protruding portion would not be in the way. After passing the sutures the stomach could be secured and the sutures then tied; those sutures lying in the way of the protruding stomach should be divided and used to bring the peritoneum and skin together on each side, and thus present a broader peritoneal surface for union to the stomach. This union takes place very rapidly; it has been found firm in nineteen hours in one case, in another in twenty-four hours, and in a third in thirty hours.[4] This being so, rectal alimentation can, in urgent cases, be supplemented by food to the stomach very shortly after the preliminary operation. If the œsophageal stricture were impermeable the stomach had better be opened; in rare cases it might be advisable to do so at once on securing the stomach, in order to prevent fatal prostration.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 3, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

ADDRESS BY THE PRESIDENT.

DR. JACOBI, on entering upon the duties of President for another two years, said that the position was not simply an honor, or otherwise he would have declined it, as there were others more worthy of this distinction; but the office was also one of grave responsibilities, and he was willing to submit to these. In his past course he had endeavored to select as subjects for the scientific discussions of the Academy such as were of general interest to the profession; leaving to the various sections, for the most part, those that were of special character. He had also taken particular pains to enlist the young men, with their enthusiasm and spirit of earnest endeavor.

In speaking of the present prosperity of the Academy, he referred to the development of nine distinct sections, now all in active operation, and stated that one hundred and twenty names had been added to the Fellowship of the Academy during the past year. During the year, also, no less than $100,000 had been donated to the building fund, and the need for more extensive and suitable accommodations than the present ones was pressing.

A COMMITTEE ON BUILDING SITE

was appointed, consisting of Drs. George A. Peters, Frederick A. Castle, and the President; who represented respectively the Council, the Board of Trustees, and the Academy at large.

DR. JOHN H. GIRDNER read a paper on

THE DETECTING AND LOCATING OF METALLIC MASSES IN THE HUMAN BODY BY THE INDUCTION BALANCE AND THE TELEPHONIC PROBE.

The induction balance, which was the invention of Professor Alexander Graham Bell, of Washington, he said first suggested itself in the summer of 1881, after the shooting of President Garfield. The attempt was made to locate the ball in his case by this means, but, owing to the crudity of the apparatus, the lack of experience in its use, and the disturbing element due to the presence of a large steel mattress on which the patient lay, which was unknown at the time, the result was unsatisfactory.

Having stated that in his opinion this apparatus would be indispensable in time of war, Dr. Girdner proceeded to describe it. An ordinary bichromate battery of six cells is used. An interrupted current is necessary, and about 600 interruptions per minute have proved the most useful for the purpose. For the induction balance two currents are required, the primary and the secondary or induced, and each current passes through two coils of wire (No. 25), one of which is twice the size of the other. The two larger coils, which are simply laid over each other, and fastened on a large

disk of wood, provided with a handle, which is called the *explorer*, and the coil of the induced current is connected with a telephonic receiver.

When no metallic substance is in the vicinity of the explorer, no sound whatever is heard by the ear placed at the telephonic receiver; but when the explorer is brought near a metallic mass the presence of the latter is indicated to the ear by the sound heard in the receiver; this sound increasing in intensity as the explorer approaches nearer and nearer the mass. The larger coils were called the exploring coils and the smaller the adjusting coils. The greatest intensity of sound is reached when the centre of the explorer approaches the nearest to the metallic body. Fortunately for the successful application of the instrument, experiment has shown that living tissue is the best conductor of the sound.

The telephonic probe was also the invention of Professor Bell. A telephonic receiver is connected with a piece of ordinary steel laid upon the surface of the body, and also with a long needle, which is to be inserted into the flesh at the point indicated by the explorer as that at which the sound in the telephonic receiver of the induction balance is most distinct. As soon as the point of the needle comes in contact with the metallic mass, a sharp click is heard in the receiver.

Colonel Clayton, a gentleman who was shot in the chest at the battle of Cedar Mountain during the late war, and still retains the ball, presented himself as a subject for illustrating the *modus operandi* of the induction balance, and by means of this apparatus the location of the ball was easily determined to be at the junction of the clavicle with the sternum.

In order to demonstrate the working of the telephonic probe Dr. Girdner employed a piece of beef, in which a mass of lead was deeply embedded, and the experiment of detecting its precise location was entirely satisfactory to all who had the opportunity of personally testing the apparatus.

Dr. Newton M. Shaffer read a paper on the use of

TRACTION IN THE TREATMENT OF CLUB-FOOT,

with a consideration of some of its mechanical principles involved, and a description of the antero-posterior and lateral traction apparatus. He said that more than ten years ago he commenced a series of experiments in connection with the treatment by traction, and that the results of these early experiments were embodied in a paper which he had published in the autumn of 1878. This was however, merely a provisional paper, and since the time of its appearance he had made many improvements in the apparatus employed. Further experience had fully convinced him of the great importance of the "pusher" principle.

Dr. Shaffer illustrated the normal foot movements by a series of diagrams. There is only one centre of antero-lateral rotation in the ankle-joint, he said, and this centre of motion is situated below the malleoli. In order to correct the deformity of talipes equinus the heel must be made to move downward and forward, and the toes must move upward and backward. Then much of the astralagus rotates around the same centre of rotation as the heel and toes, and it rotates upward and backward. The normal movements of the foot should be exaggerated, on account of the resistance which is met with.

In the conventional club-foot apparatus there are various defects. Thus, as the anterior part of the foot rotates upon its artificial ankle-joint centre, or, in other words, as we crowd the os calcis into the heel-cup, and attempt to flex the foot, the heel, unless restrained, slips forward. The attempt is made to control this movement by tying the heel down to the foot-plate and in the heel-cup, with the heel-strap. If, after this heel-strap is tied, a considerable pressure be applied in the direction of flexion (even, in many cases, after tenotomy), the further tendency of the heel (being restrained in front by the heel-strap) is to slip upward and backward away from its artificial annular ligament, ultimately, in many cases, resting on the tip of the heel-plate which forms the cup, When this occurs, all control over the foot is lost, as it turns toward that side upon which the contractions exist. One of the direct effects of mechanical flexion, as applied in the customary forms of apparatus, to overcome either a posttibial or a plantar contraction, is to crowd the tarsal bones together.

Dr. Shaffer then described his antero-posterior traction apparatus, by means of which, through the agency of an arm and screw, any desired angle of flexion or extension could be secured. The Scarpa heel-cup, which had been so long and universally employed, he said, is not necessary here, and a semicircular opening is provided for the descent of the heel. In connection with the traction heel-strap an astragalar strap is worn over a pad, and this astragalar strap is to be loosened in order to allow of rotation. When plantar contractions are to be overcome, however, the astragalar strap should not be loosened.

In equino-varus the lateral pushing force has many advantages over the lateral pulling force. Simple, uncomplicated equino-varus, he considered a rare condition. The lateral traction apparatus, which he also described and exhibited, he said, acted as a lateral pusher (evicting the foot), brought the foot up into a position of flexion, and caused the anterior portion of the tarsus to rotate outward.

When we have to do with confirmed deformity it is necessary that sufficient force should be used to overcome the resistance present; and he spoke of the great benefit which he had seen derived from the employment of exaggerated traction maintained for a few seconds or minutes, according to the degree of tolerance present, and repeated at frequent intervals. In his experience, excoriations occurred only as the result of neglect on the part of the attendants.

When the traction apparatus is used, the knife is unnecessary in many cases where it would ordinarily be required. There are, however, a certain number of rare cases which do not yield to simple traction, and in these tenotomy is demanded. In such instances, however, the patients are much more liable to complain of pain and discomfort from the wearing of the apparatus (after tenotomy), than in those which are treated by means of traction only. While there are a few cases which will not yield to traction either with or without tenotomy, Dr. Shaffer said he knew of no apparatus so efficient and complete as these traction shoes. In conclusion, he stated that nine years ago he

had predicted that tenotomy would be much less frequently resorted to than formerly, and he was glad to say that this prediction had been realized, as the foot is a more natural one when no cutting is required.

DR. RIDLON said that he had not been able to get as good results with the lateral shoe as Dr. Shaffer himself, who was remarkably skilful in applying his traction apparatus. Again, there are certain cases in which the use of traction is not followed by good results. We should be able, he thought, to judge at the beginning whether in any case traction would be beneficial or not, and the test of "point-pressure" enabled us to say whether or not tenotomy was called for. Dr. Shaffer, on the other hand, is in the habit of first trying stretching for a time, and then, if the result is not satisfactory, he performs tenotomy. It is better, in his opinion, to cut at once in those cases in which the operation is necessary.

DR. KETCH said that he had had an experience of over nine years with the traction shoe, and he desired to call attention to two points: First, the possibility of treating many cases of club-foot without an operation of any kind, and, second, the fact that the benefit to be derived from the principle of the use of intermittent force, for the credit of the introduction of which we are indebted to Dr. Shaffer, is not sufficiently appreciated. As early as 1885 Dr. Shaffer found that the danger of relapse after tenotomy, and its so-called after-treatment, was very much less if the traction apparatus was used.

DR. A. B. JUDSON said that it was clear that this apparatus of Dr. Shaffer was capable of exerting great force, and, therefore, it was especially necessary that it should be in careful hands. If, however, cases of club-foot are well managed from the first, this violence would not be required. By this he did not mean to reflect in any way upon the method of treatment described; but simply to refer to the desirability of an enlightened opinion in the community upon such subjects.

In closing the discussion, DR. SHAFFER said that he was at a loss to understand the want of success in the use of the lateral shoe, to which reference had been made. The application is simple, and it is only necessary that the shoe should accurately fit the deformity. The trouble was, he thought, that too much was attempted at first. The process of treatment must be a gradual one, with no haste and no violence. The method is a very easy one when the apparatus is perfectly adapted to the case, and just as much or as little power as is required could be used with it. In regard to the matter of "point-pressure," he said that some of his best results with traction alone had been obtained in cases in which this so-called test indicated tenotomy. For his part, he knew of no guide by means of which he could tell at first whether cutting would be required.

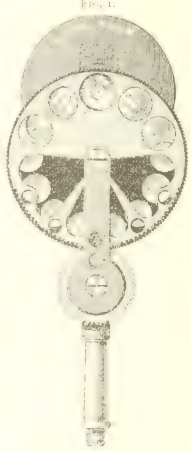
NEW INVENTIONS.

A MODIFIED LORING OPHTHALMOSCOPE.[1]

A DESCRIPTION of a disk of cylindrical lenses as an addition to the ophthalmoscope was published by the writer in THE MEDICAL NEWS of October 17, 1885, and the practical value of the addition, as well as its applicability to many of the usual forms of the instrument, was there pointed out. Some minor inconveniences in its application to the newer Loring ophthalmoscope, for which it was more especially designed, were also noted: and a modified model of that instrument, then in course of construction, was promised as free from these and other disadvantages. This new model, having met the demands of practice, is now presented.

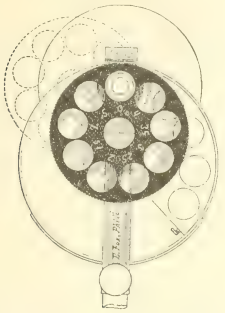
As indicated by the cut (Fig. 1) which shows it in its simpler form, without the disk of cylindricals, the instrument corresponds closely in its dimensions to the smaller model of Dr. Loring's ophthalmoscope. The main disk has twelve openings, one vacant and the others containing spherical lenses, 7 mm. in breadth, from + 5.0 — 6 D.; the supplemental disk or "quadrant" contains + 0.5 and + 13 D. on one side of its zero-opening, and the corresponding concave lenses on the other. The main disk is rotated as usual by the pressure of the finger upon its milled edge: the supplemental disk articulates with a cogwheel below it in the handle, and is moved by its rotation — spring-stops serving to centre all lenses accurately at the sight-hole. The numbers indicating the lenses in use appear at the openings near the handle, where they cannot be hidden by the addition of the disk of cylinders. This latter has been sufficiently described and its means of application to the instrument is indicated by the dotted lines of Fig. 1. It is represented in Fig. 2 as added to the usual Loring ophthalmoscope. The convex lenses thus given in unbroken series are + 0.5, 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, 5, 5.5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18; and the concaves are the same with the addition of

FIG. 1.



[1] Ophthalmological

—6.5 and 19—a series ample for all but exceptional cases; while the quadrant might be made to accommodate a —24 if desired, and thus extend the series of con-



caves to —30 D. The cylindrical lenses are *concaves* from 0.5 to 4, and furnish all ordinary sphero-cylindrical combinations.

The maximum thickness of the instrument at the sight-hole, when the cylinder-disk is added, is 10 mm., and the weight is 47.4 grammes—as compared with 7.75 mm. and 45.2 grammes of the Loring. Without the cylinders it is practically identical with it in thickness, weight, and balance—a point worth emphasizing. The cost is but slightly greater; and the increased complexity seems fully justified by the increase in efficiency.

The instrument was designed in most respects six years ago, before the appearance of other models, such as Dr. Noyes', embodying similar ideas; but is offered solely as an adaptation of the Loring instrument to the needs which the writer has felt in his own work. The practical value of the arrangement which makes the 0.5 lenses *self-centring* and always available at a touch, will be contested by no one who tries to make careful measurements with the ophthalmoscope; and, although but a small part of the long continuous series of concaves or convexes is wanted at any one time, every ophthalmoscopist has experienced the awkwardness of working with the lenses at the "break," or transition from the single lens to the compound lenses of the double disk, and will find the new model a convenience in these respects. The disk of cylinder-lenses had already proved its practical value when attention was called to it, and an additional year of use has more than confirmed the favorable opinion then held.

The change of the lower journal of the tilting-mirror into a spring-clip, permits the ready removal of the usual concave mirror and the substitution of a plane or weak-light mirror: while without it, the instrument is more readily utilized as an optometer (in the absence of the case of test-glasses), either for the subjective determination of the refraction or for measuring by neutralization the strength of other lenses—a use in which the ophthalmoscope has often proved valuable. As constructed by Mr. Fox, of 17th and Chestnut Sts., this new model will compare not unfavorably with the most perfect examples of Dr. Loring's ophthalmoscope.

NEWS ITEMS.

A Prize Essay on Hay-fever.—The Chairman of the Committee on Scientific Facts, of the United States Hay-fever Association, asks leave to submit the following to the members, and to the medical fraternity, and to all who are interested, whether as sufferers or students of this increasing malady:

At its last meeting, September, 1886, at Bethlehem, N. H., the Association decided to offer a prize for the best essay from a competent source, preferably a physician, on some question relating to *Æstivis*, or Hay-fever. The amount is necessarily small; but as the accepted essay will be published in the Association's report, when the extent of its circulation, and the character of those whom it will reach shall be considered, it is thought that the successful treatise will give to its author a reputation worth the effort.

In order to carry out the above the following is announced officially:

1. Subject of the essay, Hay-fever. (a) Its Pathology. (b) The predisposing, and the aggravating causes. (c) Advice to the sufferer.

2. The essay not to exceed *four thousand words*, and to be as practical and non-technical as possible.

3. The manuscripts to be received at the office of Samuel Lockwood, Freehold, New Jersey, not later than April 30, 1887.

4. Each manuscript to have a motto under the title, and to be accompanied with a sealed letter containing said motto, also the name and address of the author. These letters not to be opened until after the award is decided.

5. The prize to be $25. The accepted essay to be published immediately in the Association's annual report, one hundred copies to be given the author.

The Springfield, Mass., City Hospital has had bequeathed to it, in the will of the late Mr. William Merrick, a sum stated to be between $75,000 and $100,000. Together with the $25,000 received from Mrs. Chester W. Chapin, this places the institution on a good footing, and it is understood that the trustees are looking about for a new building, the present property being at too great a distance from the business portion of the city.—*New York Med. Journal*, Jan. 29, 1887.

Dr. Thomas E. McArdle has been compelled, on account of ill health, to resign the position of Professor of Surgery in the Medical Department of the National University, Washington, D. C., and Dr. Philip T. Harvey, U. S. Army, has been appointed to fill the vacancy.

A New German Monthly Devoted to Therapeutics has just appeared, edited by Liebreich, Langgaard, and Rabow. Its scope embraces original communications from celebrated clinicians, reports of the discussions and actions of societies, descriptions of new remedies and methods of treatment; its first number contains interesting matter from Kohls, Hausmann, Veit, Casper, Liebreich, and others.

BERLIN DISINFECTION STATIONS.—These stations, established November 1st, have done excellent work. The populace has availed itself of these establishments independently of police regulations.

From November 1st to December 15th, 10,593 pieces were disinfected, comprising bedding, clothing, furniture, and all articles of personal use. The material for disinfection came from 261 persons, and the cases were mostly diphtheria and scarlatina.—*Berliner klinische Wochenschrift*, January 17, 1887.

PROFESSOR JOHANN RUDOLPH RANKE.—The University of Groningen is just now mourning the loss by death of the much respected Professor of Surgery, Dr. Johann Rudolph Ranke, who, though a foreigner, seems to have endeared himself to all classes of the people. For the last eighteen months he had suffered from the effects of blood-poisoning, which had caused him continual severe pain; but he stuck most heroically to his work to the last, teaching from his bed students who were about to present themselves for examination, and, on days when he was somewhat better, going in a bath-chair to the university or hospital. Only three days before his death he performed an important operation.

THE VIENNA HOSPITAL.—From a statistical report of the great Vienna Hospital, which has just been published, we learn that during 1885, 26,448 patients were treated there. Of these, 13,000 were discharged cured and 4000 improved. Some were removed to other institutions, as many as 1000 being sent to lunatic asylums and more than 500 to the smallpox hospital. There were 2898 deaths. The total number of patients during the last hundred years was 1,654,729, amongst whom the mortality was 237,218, or 14.33 per cent. In 1885, which was the first year of the second century of the hospital's existence, the number of admissions was 8000 in excess of the annual average for the preceding hundred years, and 3300 in excess of that of the preceding ten years, the mortality being 0.95 less than that of the century, and 0.63 less than that of the last ten years.

THE HIGHER EDUCATION OF WOMEN.—In the second Lettsomian Lecture, delivered by Dr. Langdon Down, before the Medical Society of London, on Monday last, some interesting remarks fell from him in reference to the effect of the higher education of women in the production of feeble-mindedness in their offspring. Coming from so good an authority, and based as they are on an experience of infantile mental affections extending over so long a period of time, they have a scientific as well as a social interest, which justifies attention being called to them. No objection, he said, was shown to women being taught everything relating to art, music, or their emotional life, but directly attempts were made to cultivate their judgment, to teach them how to reason, to inculcate habits of self-control, the proposal was met by clamors, which, in his opinion, were not based on experience, and, so far as the etiology of feeble mindedness was concerned, were likely to be prejudicial. Still more emphatic was Dr. Down's assertion that if there is one thing more certain than another about the production of idiocy, it is the danger which arises from the culture of only one side of woman's nature. The whole gist of the matter lies in the necessity of proportioning the education given to the physical and mental calibre of the recipient. The average female mind is often assumed to be inferior in power and compass to the average male intellect, but the difference is not, according to Dr. Langdon Down, such as to render it either desirable or necessary to restrict female education to the narrow limits of the drawing-room and the kitchen. Reliable statistics on the subject are not forthcoming, and it is even difficult to imagine any which could command acceptance. The observance of ordinary care, and the mandates of elementary physiological knowledge, will, in all probability, afford as great a safeguard in this direction as they do in the region of athletic exercise for girls. Either or both may be overdone, but if this occur, it is only in consequence of inattention to, or ignorance of, this very important subject.—*British Medical Journal*, January 22, 1887.

NOTES AND QUERIES.

[illegible]

After my communication on Chloroform and Ether Deaths (in the Correspondence of THE NEWS for last week) had left my hands, I discovered that in the transcription of my rough notes the word "detailed" had been omitted in my comment on Dr. Reeve's Case IV. It should read, "there is no detailed mention of."

I have had the curiosity to look up this case, which is in the *New York Herald* for Nov. 22, 1875. The operation was done at a homœopathic college, and the physician who had his hand on the pulse testified that it was good at the moment the face turned blue. At the post-mortem, made by Drs. Cushman and T. C. Finnell, there was a strong odor of ether perceptible; the brain, lungs, liver, and kidneys were congested; the heart small and fatty. Dr. Finnell, at the coroner's inquest, ascribed the death to the action of ether on the fatty heart.

It seems to me that the supposition of the Editor of the *Boston Med. and Surg. Journal*, that the death was due to the presence of blood in the trachea, is more likely to have been correct.

JOHN H. PACKARD, M.D.

[illegible]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 1 TO FEBRUARY 7, 1887.

FRYER, BLENCOME E., *Major and Surgeon.*—Ordered to Fort Lowell, Arizona Territory.—*S. O. 20, A. G. O.*, February 4, 1887.

[illegible], *Captain and Assistant Surgeon.*—Granted sick leave of absence further extended three months on surgeon's certificate of disability.—*S. O. 29, A. G. O.*, February 4, 1887.

[illegible], *Captain and Assistant Surgeon.*—Granted leave of absence for four months, with permission to go beyond sea. To take effect when his services can be spared by his department commander.—*S. O. 28, A. G. O.*, February 3, 1887.

[illegible], *Captain and Assistant Surgeon.*—Granted leave of absence for two months, to take effect when his services can be spared by his department commander.—*S. O. 24, A. G. O.*, January 29, 1887.

[illegible], *First Lieutenant and Assistant Surgeon.*—Ordered for temporary duty as Post Surgeon at Fort Barrancas, Florida, to take effect upon the expiration of his present leave of absence.—*S.O.24, Division of the Atlantic*, February 3, 1887.

[illegible], *First Lieutenant and Assistant Surgeon.*—Leave of absence further extended one month.—*S. O. 29, A. G. O.*, February 4, 1887.

WOOD, LEONARD, *First Lieutenant and Assistant Surgeon.*—Ordered to proceed to these Headquarters, and report to the Department Commander for temporary duty.—*S. O. 12, Department [illegible]*, January 6, 1887.

THE MIDDLETON GOLDSMITH LECTURES.

Delivered under the Direction of the New York Pathological Society.

BY M. ALLEN STARR, M.D., PH.D.,

PROFESSOR OF NERVOUS DISEASES IN NEW YORK POLYCLINIC.

LECTURE II.

January 28, 1887.

MULTIPLE NEURITIS, AND ITS RELATION TO CERTAIN PERIPHERAL NEUROSES.

(Continued from page 174.)

2. *Multiple neuritis consequent upon infectious diseases*—There are a number of infectious diseases which are especially liable to be followed by the development of nervous symptoms. These are diphtheria, variola, typhoid, typhus, and scarlet fever, malarial fever, and tuberculosis. The nervous affection usually appears shortly after the period of convalescence in the acute fever. The disease may consist of a simple paralysis of the muscles in the region of distribution of a single nerve. It may affect several nerves on both sides of the body symmetrically. It may even paralyze two or more limbs. It occasionally produces sensory as well as motor symptoms in a single nerve-trunk. It may even cause a general sensory and motor paralysis of as widespread and complex a kind as that produced by chronic alcoholism. Sometimes the symptoms are chiefly of a sensory kind, and consist exclusively of pains, numbness and anæsthesia, or hyperæsthesia, in the legs, or of a loss of the muscular sense, in which case a true ataxia is the most noticeable symptom. Thus it is evident that the poison of an infectious disease may act as powerfully upon the nervous system as any other form of poison known.

It is only since the clinical pictures presented by multiple neuritis have been recognized that a question has arisen as to the part of the nervous system affected in these cases. Formerly all such phenomena were referred to central lesions; and undoubtedly in many cases this was justified, since autopsies are not wanting to prove that anterior poliomyelitis, diffuse myelitis, and hemorrhages into the cord and brain may follow the acute fevers. There are, however, many conditions which do not correspond to the types of disease produced by central lesions, and which recover with a rapidity impossible were the brain or spinal cord involved. It was these cases which raised the question of some possible affection of the peripheral nerves. And careful investigation has been rewarded by the actual discovery of lesions in them.[1]

[1] Lancereaux et Vaillard: Rev. de Medecine, 1881, p. 289, 1880, p. 1050, p. 574. Des Névrites Périphériques chez les typhoïdes, les tuberculeux et les tabétiques. Virc. Arch. de Neurol., 1886, p. 337. De la névrite segmentaire.

(*a*) Diphtheritic paralysis is probably more common than any other of these forms of neuritis. As is well known, it is usually the soft palate to which the paralysis is limited, and, as a result, difficulty in swallowing, and in speech are the most prominent symptoms. Bernhardt has found[1] that in the large majority of cases of this kind there is a loss of the patella tendon reflex, but whether this indicates any general affection of the peripheral nerves he does not venture to state. The limitation of the paralysis to the palate has been explained by supposing that the poison of the disease has a direct action upon the terminal filaments of the nerves, which in this position are, as it were, dipped constantly in the poison. This theory is supported by a case in which paralysis of the abdominal muscles was associated with diphtheritic inflammation of the navel in a newborn child. But the more serious cases prove that through the blood the poison may be carried to nerves far removed from the seat of the diphtheritic inflammation.

And the following cases demonstrate the widespread symptoms which such general poisoning can produce, as well as the nature of the lesion.

Observation XIV.—Marie S., aged thirteen, after suffering for a few days from a slight sore throat, found herself unable to see clearly because of the development of a paresis of accommodation. There followed a slowly progressing ataxia of the upper, and later of the lower, limbs, with uncertain gait, disturbance of touch, pain, temperature, and muscular senses, with delayed sensation of pain, and loss of tendon reflexes. At first she felt shooting pains in the limbs, but later these ceased. There was at no time tenderness of the nerves to pressure. After three months bulbar symptoms appeared, atrophy with paresis of the tongue, difficulty in swallowing, spasms of coughing, weakness of voice, and paralysis of the palate. The muscles of the hands began to atrophy about the time that the bulbar symptoms commenced, and soon were useless. In the atrophic muscles the faradic reaction was absent, the galvanic much reduced and very slow. Nine months after the onset she died of pneumonia.

The autopsy showed the brain and spinal cord to be normal. In all the peripheral nerves of the extremities, as well as in the hypoglossal and recurrent laryngeal nerves, well-marked atrophic degeneration was found, with destruction of axis-cylinders and medullary sheaths, and with thickening and increase of nuclei in the connective tissue sheaths.[2]

Observation XV.—Male, aged seventeen, after an attack of diphtheria grew gradually weaker and weaker, developed paralysis of the uvula, and paralysis with some atrophy in the muscles of all the limbs, and a slight paralysis of the face and tongue. There was no real ataxia, the muscular sense being normal, but the

[1] Virch. Archiv., 1885, Bd. 99, S. 393.

[2] Kast.: Deut. Arch. f. klin. Med., 1886, Bd. xl, S. 41.

weakness of the muscles interfered with all accurate movement and caused trembling. The eyes were not affected. There was a slight decrease of tactile sense all over, but pain sense was slow and imperfect. The reflexes were lost, electric reaction was normal in all muscles except the palate, in which RD was found. The sphincters were unaffected. The paralysis involved the respiratory muscles three weeks after the onset of the disease, and caused his death.

The autopsy showed extensive parenchymatous neuritis in all the peripheral nerves. The various stages of degeneration were found side by side in many nerves, and all degrees of degeneration were discovered. The nerves of the extremities, as well as the phrenics, showed these changes. Some nerve-fibres had simply lost their myelin sheath, others were reduced to a series of granular corpuscles; others consisted only of the empty Schwann sheath, whose nuclei were numerous. In many nerves the lesion involved only a few segments, and was not continuous through the entire length. At places circumscribed thickening of the endoneurium produced nodular appearances in the course of the degenerated nerve. Here congestion and emigration of leucocytes were found. The perineurium was unaffected. In almost all the muscles of the extremities and trunk such degenerated nerve-fibres were found. The cutaneous nerves were similarly affected, but to a less degree. The nerve-trunks were but slightly affected, as were also the nerve-roots. The spinal ganglia and cord were normal.[1] The limitation of the degeneration to single segments has also been noticed by Gombault and by Pitres et Vaillard.[2]

Observation XVI.—A boy, aged eight, developed paralysis of the soft palate one week after an attack of diphtheria. This continued for one month, when there suddenly appeared a weakness of all the extremities, and some disturbance of sight. Examination of the eyes showed a complete paralysis of all the recti muscles, with double ptosis, the accommodation and pupil reactions being preserved. The right side of the face was paretic. There was a very marked ataxia in all the limbs. It was with difficulty that he could carry food to his mouth, and he walked with much staggering, and with legs wide apart. Power and nutrition of the muscles were normal, and there was no change in their electric contractility. The tendon reflexes were absent, but the skin reflexes were preserved; and there was no disturbance of sensation, or of bladder and rectal functions. The symptoms all increased for ten days, and then respiratory paralysis caused his death.

It was possible to examine the brain only. The small vessels and capillaries were engorged, and the perivascular spaces full of emigrated corpuscles, while here and there small capillary hemorrhages were found. The vessel walls were not affected, and there were no thrombi discovered. The nuclei of the cranial nerves showed no changes. Both oculo-motor nerves were the seat of very great changes. The myelin sheath of individual nerve-fibres absorbed the carmine stain. In many fibres no axis-cylinder was to be seen. In others the cylinders were swollen or atrophied, presenting variations in size. The number of nuclei of the endoneurium was greatly increased, and among them large granular corpuscles were discovered. The lesion, therefore, which had caused the ocular paralysis was a diffuse neuritis.[3]

A similar affection of the ocular muscles, associated with general weakness, has been reported by Utthoff,[4] which developed two weeks after an attack of diphtheria, in a boy, ten years of age, and at the end of three months had completely recovered. In this case all reaction of the pupils in accommodation was lost, but the light reflex remained. The eye symptoms were attended by some paresis, especially in the legs below the knees, but the muscles were not atrophied, nor was their electric contractility altered. There was a very marked tenderness along the course of all the nerve-trunks. After recovery was complete the knee-jerk returned.

I have seen a case which resembled this quite closely, and inasmuch as paralysis of all the ocular muscles appears to be a rather rare affection, the case may be worthy of mention here.

Observation XVII.—A boy, aged thirteen, after an attack of diphtheria developed paralysis of the soft palate. One week after the parlysis of the palate he noticed a disturbance of vision, which proved on examination to be due to a total paralysis of all the muscles of the eyeballs. The pupil reflex to light was preserved; but as he could not converge the eyes there was no reaction in accommodation. This paralysis of the eyeballs came on within twenty-four hours, and at the same time he developed a very marked degree of ataxia. He swayed in standing with eyes closed, and his gait was exactly like that of a well-marked case of tabes. The motions of the hands were also disturbed, and all the tests demonstrated an extreme degree of incoördination. The knee-jerks were lost; the skin reflexes were present. In addition to the ataxia there was actual weakness of the muscles, which was more evident in the arms and hands than in the lower extremities. He had formication in the legs, but not in the hands, and there were no lightning pains. He had great difficulty in swallowing solids as well as liquids, which seemed to point to some involvement of the muscles of deglutition as well as of the soft palate. This condition remained stationary for about three weeks, and then all the symptoms began to pass off gradually. His recovery was not complete until six months after the onset.

The prognosis in cases of diphtheritic paralysis is usually very good, the fatal cases here cited being rarities. The treatment consists in general tonic medicines, and the application of electricity to the limbs in the same manner as in other cases of neuritis.

(*b*) Neuritis following variola is a rare complication, and the following case is the only one on record in which an autopsy proved the seat of the lesion:

Observation XVIII.—A young man had varioloid in November, 1881, and while convalescing, six weeks later, began to suffer from severe pains in his four extremities, especially in the joints of his arms, which were diagnosticated as rheumatic, although there was no fever. Soon after there followed a true paresis, with progressive atrophy of the muscles of forearms and legs. The muscles at the same time became very tender to

touch or pressure. The tendon reflexes were much diminished. Reaction of degeneration developed in all the paretic muscles. The pains in the joints and limbs continued, but were less severe than at the outset. The sensibility of the skin was about normal. The nerve-trunks were tender to pressure. Profuse, offensive perspiration in all four extremities was a distressing symptom. There was no tendency to bedsores, but an extensive pemphigus developed in the legs, and then the pains became more severe. The patient died in July, 1882, of pneumonia.

Autopsy showed the brain œdematous, and the cord in a state of hypostatic congestion. The pathological changes of importance were found in the nerves and muscles. The majority of the nerves of all the extremities were found in a state of degeneration and atrophy. There was marked degenerative atrophy and fatty degeneration of the muscles.[1]

(*c*) It is still somewhat a matter of conjecture whether cases of paralysis following typhoid, typhus, and malarial fevers are due to an affection of the peripheral nerves or of the spinal cord. The researches of Pitres and Vaillard[2] have shown that extensive degeneration of peripheral nerves is to be found in the bodies of patients who have died of typhoid fever, and they have also demonstrated that these fevers are often followed by local neuritis as a sequel. Cases of multiple neuritis with autopsies have not as yet been reported after typhoid or typhus: but Buzzard has recently recorded[3] two cases, following malarial fever, in which all the symptoms pointed to an affection of the peripheral nerves. In this country Gibney has described several cases of paralysis of the extremities, of sudden onset, rapid course, and prompt recovery under large doses of quinine, which he considered malarial. Probably the following case, which was kindly sent to me by Dr. L. E. Holt, was of this nature.

Observation XIX.—Peter S., aged ten, a healthy boy, was suddenly seized with a chill and fever, and with pains of a severe kind in both legs, associated with weakness so that he could hardly stand. The pain was referred to the sciatic nerves, and was accompanied by numbness and tingling of the feet and legs. There was marked tenderness both in the course of the sciatics and in the muscles of the thigh and leg. There was loss of tendon reflexes, preservation of skin reflexes, and marked paresis in all the muscles of the legs, so that he required help in walking. There was no ataxia, and no incontinence of urine. The symptoms lasted about twenty-four hours, and then decreased in severity gradually during the following day, but recurred on the third, and, after a remission, on the fifth day, with lessened severity. The periodicity of the affection and the rapid cure under quinine left no doubt as to its malarial nature. During the third day, at the time when I saw him, there was redness along the course of the sciatics, and in the region of the right median nerve, and extreme tenderness along these nerve-trunks, in addition to the symptoms mentioned. The electric condition was, unfortunately, not tested; but in Westphal's case faradic contractility was totally abolished during the attack.[1] In this case the active manifestation of the malarial poisoning was by general neuritis. In Buzzard's cases the malarial attacks preceded the nervous affection. The tenderness in muscles and nerves left no doubt regarding the peripheral nature of the disease.

And here I may suggest that it is possible that many minor nervous affections of transient nature and of malarial origin, if more carefully examined, will be found to be due to some abnormal condition in the peripheral nerves. I allude not only to neuralgiæ, but also to visceral neuroses, whose clinical features have been so graphically described by Dr. Clifford Allbutt,[2] and to numb fingers and toes, and to hyperæsthetic and painful areas on the surface, and that host of symptoms of a local character so often carelessly ticketed neurasthenia and dismissed from consideration as soon as named. There is much in the study of the phenomena of neuritis to enforce this suggestion, which cannot be developed here.

(*d*) We come, lastly, to those cases of multiple neuritis which occur in tubercular patients, or in those who have had syphilis. If a review of the cases of multiple neuritis already cited be made, it will be found that quite a number of the patients died of phthisis. This was true of the cases of Joffroy, Eisenlohr, Strümpell, Webber, and Müller. Oppenheim[3] has reported cases of multiple neuritis in tubercular patients which went on to recovery. The following case died:

Observation XX.—A young girl, who had had syphilis and was suffering from phthisis, took a severe cold and began to have pains in the joints, weakness, and numbness of the lower extremities. The weakness of the legs increased rapidly, and was attended by rapid diffuse atrophy. The same symptoms soon developed in the arm. Four weeks after the onset partial RD was present in all the extremities, and a total paralysis of the legs, and nearly complete paralysis of the arms were present. In the course of the disease, which lasted five months, there was little pain, but great tenderness of the muscles and hyperæsthesia of the skin. The sensation was diminished in feet and hands, but this was slight in comparison with the motor symptoms. The paralysis finally attacked the trunk muscles and the diaphragm, while the beginning of rapid heart action was thought to indicate paralysis of the pneumogastric nerve. Great prostration, delirium, incontinence, bedsores, and œdema of extremities, with fever, preceded death.

Autopsy: High degree of degeneration of the peripheral nerves, including the phrenic and pneumogastric, was found, with a moderate degree of atrophy of the muscles. Cord normal, anterior motor roots normal. The changes in the nerves were similar to those after section, viz., a simple degeneration of the fibres with some increase in the connective tissue, but there were no evidences of changes in the vessel-walls, no infiltration with cells. The nerves contained very few normal fibres. The myelin sheaths were found in all stages of destruction, down to an entire absence of contents of the sheath of Schwann. Throughout the fibres fatty and granular masses were found. The sheath of

Schwann did not, however, show an increase of nuclei.[1]

[illegible] years ago, to a tubercular spinal meningitis, as would many of the other cases already alluded to. It is not my purpose to dispute in any way the fact that many cases of paralysis occurring in the course of phthisis are due to lesions of the central nervous system and its membranes; but I desire to emphasize the fact that a multiple neuritis may produce paralysis in tubercular individuals, and the importance of appreciating this possibility cannot be too strongly urged, since the treatment, as well as the prognosis, will differ widely according to the diagnosis made. It has been known for some time that local neuritis may complicate phthisis, and the researches of Pitres and Vaillard have recently confirmed this fact. But the complication of multiple neuritis is one not mentioned in the text books, and yet is one which is by no means rare. It seems not unlikely that some of the nervous symptoms in consumption, formerly considered functional, may be traced to this affection.

Although syphilis has been described as a cause of neuritis, I cannot find that the lesion in the few cases examined has had the peculiar characteristics of syphilitic lesions elsewhere in the body, and therefore it seems to me doubtful whether we are justified in describing a syphilitic multiple neuritis. Further facts are needed to establish its existence.

(*c*) It only remains to consider briefly the epidemic form of multiple neuritis, and our study of the infectious cases will be complete.

In 1882 Professor Scheube, of Tokio, Japan, called the attention of European physicians to the existence of a peculiar affection prevailing among the Japanese.[2] It was called kakke; from two Chinese words—kiaku, meaning legs; and ke, meaning disease. It had been known among the Chinese for centuries, being mentioned by name in Chinese medical books written 200 years before the birth of Christ, and fully discussed by an eminent author in 640 A.D. It ceased, however, to prevail in China about two hundred years ago, and its ravages are now confined, according to Scheube, to Japan. There its importance is considerable, since it is so prevalent that in 1877 14 per cent., and in 1878 38 per cent., of the men serving in the army suffered from it. It is considered a miasmatic infectious disease by Scheube, although an eminent Japanese authority considers it due in some way to the diet of rice. That diet has something to do with its occurrence is proven by the fact, communicated to me by Dr. Wallace Taylor, that since wheat has been substituted for rice in the diet of some of the barracks and prisons in Japan, the disease has been less common. It occurs in epidemics, but is always endemic in Japan. It does not attack Europeans. It affects females rarely, only 9 per cent. of the cases being in women; and it is the youth of the land, between the ages of sixteen and twenty-five, who are attacked. Exposure to damp and cold in crowded dwellings, such as barracks, increases the liability to the affection. The majority of the cases occur during the hot months, but some are always under observation. This disease is not, however, confined to Japan. It has been observed for many years in the islands of the Pacific Ocean, in India, Ceylon, on the west coast of the Red Sea, in Borneo and New Guinea, in Brazil and Cuba, and its prevalence in the Dutch possessions in the China Sea has made it familiar to physicians from Holland who have visited these colonies. It is there known under the name of beri-beri. It is endemic in these regions, but occasionally occurs as an epidemic. An interesting account of such an epidemic, occurring in 1882–83 in Manila, the chief city of one of the Philippine Islands, has been given by Dr. Koeniger.[4] It appears that in the fall of 1882 an epidemic of cholera occurred in Manila of such severity that 20,000 persons, in a population of 400,000, were affected. As a precaution against this disease, the native population lived for several months almost exclusively upon rice, refusing to eat fruit or fish, which are their other chief articles of diet. As the epidemic was subsiding a terrible cyclone devastated the city, destroying the light wooden houses, and leaving 60,000 families homeless; and these poor people were exposed for several weeks to the inclemency of the weather, which at this time of the year is rainy. A few days after the cyclone the epidemic of beri-beri began, and as the disease had never before appeared in Manila, the unknown affection excited great alarm. This was increased by its fearful mortality, 60 per cent. of the early cases proving fatal. Europeans were exempt, with two exceptions, and the Chinese population did not suffer greatly, but among the natives the epidemic was widespread. Thus, in one suburb of Manila, of 25,000 inhabitants, 300 died in the course of eight weeks. Men and women were equally affected, and persons of all ages, except young children, were attacked. The disease terminated fatally in from ten days to five weeks after its onset; but as time went on, the proportion of recoveries increased, and by the end of March, 1883, it had almost disappeared. The months from October to March are the dry, cool season in the Philippine Islands, although the climate is tropical. Exposure to heat could hardly be considered a cause of this epidemic, but whether the exposure to cold and damp, or the diet of rice, or the transportation of some infectious agent by the cyclone was the cause, gave rise to much discussion, and could not be determined.

Sporadic cases of beri-beri, or kakke, occasionally appear in our hospitals, usually in the persons of Chinese or Malay sailors, or in the persons of travellers from tropical climates who have been exposed to the infection in the place from which they came. Three such cases have recently been reported by Dr. Seguin, of this city,[5] in patients who came from the West Indies, and a case observed in Bellevue Hospital, by Dr. J. West Roosevelt, was discussed in the Academy of Medicine recently. In 1881 a Brazilian naval vessel entered San Francisco with a large number of the crew affected by the disease. They were sent to the United States Marine Hospital, and attended by Dr. Hebersmith, who gave an interesting account of the circumstances leading to the development of the disease, in the United States Marine Hospital Report.[3] From this report the accompanying map is taken, which demonstrates the localities in which beri-beri is endemic.

[1] [illegible] Arch. f. Psych., 1883, [illegible]

[illegible]

[illegible] Deut. Arch. f. klin. Med., xxxiv

[illegible] [illegible] November 11, 1882.

[3] Marine Hospital Report, 1882.

Only last year a commission was appointed by the Dutch Government to investigate the subject of its nature, and the recently published report contains the following statements:[1] The disease is caused by a micro-

Sketch Map indicating the Geographical Distribution of Beri-beri. (From United States Marine Hospital Report, 1881.)

organism resembling the bacillus of splenic fever, though somewhat smaller, which colors with fuchsin and gentian-violet, and can be seen with a power of 560 degrees. These bacilli are found in the blood, lungs, heart, brain, cord, and nerves of the patients, and can be cultivated outside of the body. The germs infect wooden dwellings chiefly. They may be conveyed by articles of clothing, and probably enter the body by the lungs. Direct contagion has not been observed. A potent predisposing cause to their reception in the body and to the development of the disease is lack of nutrition, consequent upon exposure to damp and to cold, and upon insufficient or bad food. It must, however, be added that a most thorough examination in Dr. Roosevelt's case, by Dr. Prudden, failed to reveal the presence of such bacilli.

In the light of these recent investigations a new view is taken of an epidemic of a peculiar kind which occurred in France in 1828. Buzzard has found an account of this, prepared by Graves, in which the symptoms are so fully detailed as to leave no doubt that it was an epidemic of multiple neuritis.[2]

The cases of beri-beri are divided into two general classes, according to their severity.

There are, first, slight cases, in which the onset is gradual, being usually preceded by a little fever, coryza, and conjunctivitis, which cease when the actual symptoms commence. The patient first notices a weak and heavy feeling in the legs, and finds that he tires so easily that he cannot walk as much as usual. The tired feeling is soon associated with numbness and pain in the legs, and with a slight œdematous swelling. Then, if not before, palpitation of the heart, oppression and weight in the epigastrium, loss of appetite, and general malaise are felt, and the patient finds it necessary to apply for treatment. An examination then shows some diminution of power in the feet and legs, and also in the hands, with loss of tendon reflexes, and much tenderness in the muscles, which show a diminished electric excitability. There is never any ataxia, though the patient sways when his eyes are closed. There is discovered a slight degree of anæsthesia, of irregular distribution, chiefly in the legs and in the radial nerve region on the forearms. Though the patients look pale it is usually impossible to find anæmia by examination of the blood.[1] The circulation in the extremities is sluggish. The heart is irregular and rather rapid, and the œdema of the extremities indicates a failure of its power. Dr. Wallace Taylor[2] finds that a sphygmographic tracing is characterized by a sudden high upstroke in ventricular systole, by a precipitous descent from the apex of the percussion wave, and by dicrotism. Beyond this point these cases, which make up the majority, do not advance. They usually recover in a few days, or at

[1] Deutsche med. Woch., December 9, 1886 (an abstract only is given). See, also, Harada: Neurol. Centralbl., 1885, p. 326.

[2] Buzzard: On Paralysis from Peripheral Neuritis, p. 37.

[1] Studies in Japanese Kakke, by Wallace Taylor, M.D. Osaka, 1880.

most a month; although a few become chronic and require several months before the cure is complete.

There are, secondly, severe cases. These may present three different types. There is the atrophic or dry type, in which, after an onset similar in nature to that in the slight cases, but much more rapid, the weakness develops into a true paralysis, associated with marked wasting of the muscles and reaction of degeneration, with great diminution of galvanic excitability. Within a week the patient has to go to bed, and then the paralysis soon spreads from the legs to the arms, and may involve the trunk and even the face. The entire muscular system wastes away till the patient is a mere skeleton. In addition to the motor symptoms there is great sensory disturbance. The suffering from pain, paræsthesiæ, and general muscular tenderness is extreme, and the patient lies totally helpless and unable to tolerate the lightest touch. The skin may be glossy. There is usually some anæsthesia, but it is never complete, although it may involve the entire body. The temperature sense is seldom affected. Pain may be delayed in transmission. There are no gastric symptoms and no œdema. Some cases prove fatal from general exhaustion, or intercurrent disease, but the majority recover after a convalescence which lasts a year or more, during which the muscular system is rebuilt.

There is, secondly, the hydropic or wet type. In these heart-failure appears early, and is associated with a marked decrease of arterial tension and much œdema of the entire body, the effusion into the cavities being added to that beneath the integument. The swelling of the œdematous parts conceals the atrophy which is going on in the muscles, but this is indicated by the paralysis, which is as severe as in the preceding form, and it becomes evident during recovery when the œdema has subsided.

There is, thirdly, the acute pernicious type. In this all the symptoms of the two former types appear in rapid succession, and, in addition, gastro-intestinal symptoms and a suppression of urine combine to make the condition an alarming one. Effusions into the pleura and pericardium appear early. The pulse becomes small and irregular, and cyanosis indicates the heart-failure which precedes death.

In this form the disease may run its course in two weeks to a fatal termination. This was the form which chiefly prevailed in Manila, the cases of the atrophic form being the ones which recovered.

The severity differs much in different epidemics, the mortality varying from two per cent. in Japan to sixty per cent. in Manila. It is usually not above three per cent. In all the forms there is some danger of a sudden heart-failure, and this is usually the cause of death.

The morbid anatomy of the disease is, primarily, a multiple peripheral neutritis, with, secondarily, numerous organic changes in various organs, none of which, however, are essential to the disease.[1]

While we cannot join in the wish expressed by an enthusiastic German author, that the disease may soon become a familiar one to those outside of Japan, we cannot pass it by without a brief reference, especially as it resembles in so many of its features, as well as in its pathological basis, the condition which has occupied our attention at present. And it may not be unprofitable to obtain a clinical picture which differs somewhat from that already viewed, in connection with the forms more familiar to us, in order to detect sporadic cases of the disease, if such should appear among us. As to its treatment, it may be mentioned that quinine failed to influence its course, and that heart stimulants to combat the dangerous complications, hypnotics to counteract the pain and insomnia, and general tonic treatment have proved of the greatest service. Change of climate often is attended by recovery. In the stage of recovery electricity and massage have been employed with advantage.

ORIGINAL ARTICLES.

THE SURGICAL TREATMENT OF DISEASES OF THE GALL-BLADDER.[1]

[redacted], M.D.,
[redacted]

Gall-stones in the human subject are not of rare occurrence. They are less frequent in men than in women. Stein[2] collected 620 cases, of which 377 (61 per cent.) were in women, and 243 (39 per cent.) in men. They occur mostly after the age of thirty, and cases are rare below that age.

The etiology of gall-stones is as yet rather obscure. Although errors in diet—too much meat-diet, for instance—peculiarities in the nature of the soil in certain localities, sedentary habits, lacing, etc., may have some influence upon the formation of gall-stones, their origin is, perhaps, referred with more justice to a too small number of daily meals, in consequence of which the gall-bladder is less frequently emptied than it ought to be.[3]

Gall-stones may exist in the body without giving rise to any symptoms whatever. We often find them on the dissecting-table in subjects in whom, during life, they caused no inconvenience whatever. They first become of importance, if, from some cause or other, they start from their place of origin, giving rise to excruciating pains, and occasioning conditions which, in their consequences, are exceedingly dangerous to health and life. Death due to gall-stones is not very uncommon. The treatment of cholelithiasis, or gall-stone disease, by internal medication has been unsuccessful and hopeless, and yet, until a few years ago, no attempt was made to resort to the knife to cure a disease with which internal medicine was unable to cope.

Fear of fatal peritonitis, difficulty of diagnosis, and the severity of the operation, were the reasons which deterred surgeons, and left the field to internal medicine to ease the unfortunate patients by opiates, etc.

With Sir Joseph Lister's introduction of antiseptic surgery a new era appeared. Step by step opera-

[redacted] Medical Society, St. Paul, M[redacted]

tions, each surpassing the other in boldness and success, were performed; the abdomen with all its contents was successfully made subject to the surgeon's knife; and operations, but a few years ago considered absurd, have been legalized, and proved the means of saving many lives. Thus, by gradually extending the limits of abdominal surgery, the diseases of the gall-bladder and liver were finally made amenable to surgical treatment.

I do not wish it understood that surgical interference is necessary in all cases of gall-stones; it is only required where their dislodgement and subsequent obstruction to the biliary canals cause dangerous conditions which internal medicine is unable to avert, and which, as a rule, without surgical aid, will sooner or later cause the death of the patient.

But further, as any person suffering from gall-stones is at no time secure that on their way from the gall-bladder to the bowel they may not become arrested in their passage, thus causing obstruction and its consequences, which are so eminently dangerous, would it not be proper and conservative surgery to operate early, thus sparing the patient days of untold agony, and saving many a valuable life?

What surgeon would nowadays allow a woman with an ovarian tumor to die without giving her the chance of an operation? Where are the contraindications to ovariotomy if performed by a competent surgeon? If we look back ten or twenty years, and see a mortality of over thirty per cent. after ovariotomy reduced nowadays to almost none; if we consider how many thousand women have been saved from death by this one operation, and if we consider that cases of cholelithiasis are nearly as frequent as ovarian tumors, the questions arise: Why are so few operations upon the gall-bladder performed? What is their death-rate, and what is the result?

The reason so few operations are performed is because of the difficulty of diagnosis, the tendency to treat gall-stone disease by internal medication, and in an insufficient understanding by the profession at large of the possibility of successful surgical treatment. How many cases of chronic colic, gastralgia, neuralgia of the liver, and jaundice, are cases of gall-stones?

The death-rate after operations upon the gall-bladder is not so high as that after ovariotomy at its infancy, and with a better understanding, and with experienced operators, it will probably become as low. The results compare favorably with those of ovariotomy—a complete restoration to health is obtained.

The history of the surgery of the gall-bladder presents a great similarity to that of ovariotomy.

Hippocrates, Galenus, and Aretæus gave descriptions of gall-stones and diseases dependent upon them. The eminent French surgeon, Petit,[1] in the last century proposed an operation similar to lithotomy for the removal of gall-stones. If the gall-bladder was dilated and adherent to the abdominal walls, it was punctured, or fistulæ were dilated by tents and through these openings the stones were extracted with the aid of long forceps. In this way Vogel, a surgeon of Lübeck, in the last century, thought he had performed one of the "very finest surgical operations."

Another hundred years passed by until Dr. Marion Sims[1] planned and performed cholecystotomy in a case of dropsy of the gall-bladder due to gall-stones. This was in April, 1878. His patient died in nine days from exhaustion and protracted hemorrhages; still he showed the feasibility of the operation, at the same time teaching the valuable lesson not to wait until the patient's strength becomes exhausted or his blood bile-poisoned. Kocher,[2] in June, 1878, was the first who performed this operation successfully; his patient recovered in five weeks.

Musser and Keen[3] were able to tabulate up to October, 1884, thirty-five cases with ten deaths. Of this number six, which were cases of cholecystectomy, or extirpation of the gall-bladder, ought to be excluded. Five were reported by Tait in the *British Medical Journal* of May 3, 1884. No names of operators are given or other details, but three deaths and two recoveries are tabulated. The other one was Langenbuch's, No. 13 of Musser and Keen's table. This leaves twenty-nine cases, with seven deaths, reported from all sources up to October, 1884. Since then there are recorded successful cases: Tait seven,[4] Courvoisier one,[5] Trendelenburg one,[6] König one,[7] Böckel one,[8] Parkes one,[9] Carmalt one,[10] Hutchinson one,[11] Ohage one,[12] Robson two.[13] Fatal cases: Parkes two,[14] Lange one,[15] and Wetzel one.[16] Making in all fifty cases with thirty-nine recoveries and eleven deaths—a mortality of twenty-two per cent. These were all cases of cholecystotomy or *in*cision of the gall-bladder in contradistinction to the cases of cholecystectomy or complete extirpation of the gall-bladder, which I shall give further on.

I would like to draw attention to the difference in these two words. Their framing, composition, and designation are as clear and precise as can be. Few technical terms correctly explain as fully and anatomically their meaning as cholecys*to*tomy and cholecys*tec*tomy do, and yet in looking over the literature of the subject there is as much confusion in regard to their understanding as there is regarding Tait's and Battey's operation.

Cholecystotomy: χόλη, bile; κύστις, bladder; τέμνω, cut—*i. e.*, cutting the gall-bladder.

Cholecystectomy: χόλη—κύστις—ἐκτέμνω, to cut *out*—*i. e.*, cutting *out* the gall-bladder—extirpation.

Case I. *Cholecystotomy; impaction of stone in the common duct; empyema of gall-bladder; removal of forty-four stones; recovery.*—Mrs. Johanna S., Swede, æt. forty-two, married, mother of several healthy children, called at my office, February 23, 1886, and gave the following history: Had been more or less of an invalid for the last twenty years, suffering, at times, excruciating pains, referred to the right hypochondrium, extending to the right shoulder, and clear across her body. Paroxysms of pain of variable duration, often lasting for weeks, sudden in onset and disappearance. Had often been jaundiced. Two weeks prior to my seeing her she had another attack, accompanied and followed by chills, and the pain increasing and being of a more severe character than ever before, she was removed to St. Paul, a distance of forty miles, and brought to my office for treatment.

On personal inspection I found a slender, emaciated woman, whose face wore an expression of severe suffering; skin slightly icteric; pulse feeble at 120; temperature, 38° C. (101° F.). In the right hypochondriac region a tumor, about the size of a fist, could be felt, which was slightly movable, and which followed the respiratory movements of the liver. By palpation and percussion it appeared adherent to this organ. Pressure upon it, no matter how light, caused pain and nausea. The shape of the tumor was oviform. Fluctuation could not be detected. Urine showed the presence of bile. She had also suffered from dyspeptic symptoms, and the feces were clay-colored. Other organs healthy.

Diagnosis.—In consideration of her history, which was very intelligently given, and the results of the present examination: Cholelithiasis, impaction of a stone in the ductus communis (icterus and enlargement of the liver), beginning abscess formation (chills, elevated temperature), and enlargement of the gall-bladder.

I proposed an operation to her, to which she gave her consent. She entered the St. Joseph's Hospital, of this city, the same day, and the next morning, February 24th,[1] I operated, assisted by Drs. Nelson, Schulin, and the house-surgeon, Dr. Thompson, in the presence of Drs. Murphy and Hoyt, under strict antiseptic precautions, except spray. Temperature of operating room 90° F. Ether narcosis. Vertical incision about six inches long at outer border of right rectus muscle, beginning above at the margin of the eighth rib. After all hemorrhage, which was profuse, was controlled, I opened the peritoneal cavity in the usual manner, and encountered a mass which was firmly adherent to the liver, colon, and all neighboring organs. It was impossible to differentiate one part from another, to such a degree had inflammatory changes during a disease of twenty years' standing effaced all anatomical relations.

After considerable careful and difficult work I was able to expose the lower anterior part of what seemed to be an enlarged and thickened gall-bladder. Further examination proved this to be the fact, and not daring to make an incision at once into the bladder, fearing, in the first place, excessive hemorrhage into an open peritoneal cavity; and, secondly, not being certain that stitches would hold in the soft mass while trying to sew it to the abdominal wound, I concluded to fasten the gall-bladder in the abdominal wall unopened, and wait before opening it until adhesions between it and the abdominal wound had formed. I introduced my hand again, and tried to get above the whole mass, hoping I might still be able to separate the gall-bladder, and then to extirpate it, but it was impossible, and the hemorrhage was so profuse from the torn adhesions that I had to abandon the object. I then sewed the edges of the peritoneum to the abdominal wall, slightly everting them, and then closed the upper part of the wound by deep and superficial silk sutures.

The lower part of the wound, about two inches, where the exposed gall-bladder presented, was left open, and here I tried to fasten it to the abdominal wound by a few stitches. But every stitch tore through, no matter how carefully knotted. Nothing was left to do but to pack the wound until adhesions had formed. After cleaning the wound with a 1 : 2000 corrosive sublimate solution, and dusting it freely with iodoform, I laid some iodoform cotton, twisted into an oval shape, around the abdominal wound, thus pressing the wound down upon the edges of the gall-bladder, holding it in position by a large pad of absorbent cotton, and an abdominal binder, well tightened. The operation had lasted about three-quarters of an hour; there was no shock.

Patient was put to bed, and hot bottles put to her feet. She reacted well from the ether, complained of no pain, and felt quite comfortable. Diet for the first three days: Cracked ice, iced milk, coffee, and beef-tea. Temperature gradually rose until it reached 103° F. on the fourth day at 6 P.M. (aseptic fever). No sign of peritonitis, or even peritoneal tenderness. Bowels were moved by clysma on the fourth day, and were clay colored, showing that the obstruction still existed. Temperature gradually declined until it reached nearly normal on the seventh day.

On the morning of March 3d, the eighth day after the operation, I removed the dressing for the first time, and found the upper part of the abdominal wound healed by first intention, and firm adhesions between the gall-bladder and lower part of wound.

Assisted by Dr. Nelson, the house-surgeon Dr. Thompson, and the Sister in charge, I made a simple incision through the walls of the gall-bladder—which were more than half an inch thick—large enough to admit a finger, and evacuated about half a pint of greenish-looking pus. On introducing my finger, I could feel the stones on the bottom of the sac, and with the aid of a pair of forceps I removed forty-one of them. Having emptied the gall-bladder of all its contents, I next examined the ducts with a tin sound and encountered another large stone in the common duct. While attempting to extract this, it broke, and I had to remove it piecemeal. After this the ducts were free and patulous, and I could pass the sound into the duodenum. The sac was washed out with a 1 : 3000 corrosive sublimate solution, a

[1] Reports, St. Joseph's Hospital, St. Paul, Minn., 1886.

drainage tube put in, and a dressing of absorbent cotton applied. This second operation was done without any narcosis; the pain was insignificant.

On the third day there was a rise of temperature to 101° F. The dressing was changed, the cavity washed out as before, and two more stones removed. After this the temperature and pulse were normal, appetite good, bowels regular, and feces of natural color. Patient sat up on the twelfth, and went out on the fourteenth day after the first operation. The dressing was changed every day, and the sac washed out with a weak (1 : 6000) corrosive sublimate solution. There was a little discharge of bile and mucus. Drainage tube removed on the fifteenth day; wound closed rapidly.

Three weeks after the first operation the wound had completely healed, with the exception of a pin-hole fistula, which discharged a small quantity of bile-colored mucus daily. After staying a few weeks in the hospital, the patient went home and assumed the duties of a housewife, being in every way able to do her work, which for many years her disease had obliged her to forego. She has called on me several times since, and enjoys perfect health, but the fistula—which now and then closes—at times becomes painful, reopens, discharges a small quantity of mucus, and then closes again.

Case II. *Cholelithiasis; cholecystectomy; impaction of stone in cystic duct; hydrops of gall-bladder; complete removal of gall-bladder with 135 stones; recovery.*—Mrs. Lena A., Swede, æt. thirty-five years, married, multipara, called at my office on September 23, 1886, complaining of constant pain in the right hypochondriac region, extending to the right shoulder and stomach. This pain, which commenced about three months ago, had been preceded for the last three years by often repeated attacks of "colic" of variable intensity and duration. The pain always started from the right side. She had several times been jaundiced, and suffered considerably from deranged digestion.

On examination I found a strongly built, well-proportioned woman, with a clear, not icteric skin. In the right hypochondriac region an oblong tumor could be felt which was freely movable and painful to the touch. Palpation and percussion proved its upper portion to be in contact with the liver, while its lower end almost reached the iliac fossa and could be moved across the median line. The tumor followed the respiratory movements of the liver. There were dilatation and chronic catarrh of the stomach. Feces of natural color. Urine normal. All other organs healthy.

Diagnosis.—Cholelithiasis. Enlargement of gall-bladder due to obstruction of cystic duct by a stone. The possibility of the tumor being a movable kidney or an echinococcus was considered.

Operative treatment was proposed and readily accepted, and the patient was conveyed to St. Joseph's Hospital the same day. The following morning, Sept. 24, 1886, I operated, assisted by Drs. Nelson, Schulin, Dedolp, Jr., Denny, and the house-surgeon Dr. Welsh, under strict antiseptic precautions, no spray. Room temperature about 90° F. Ether narcosis. Vertical incision about six inches long on outer border of right rectus muscle, beginning above at margin of eighth rib. Very little hemorrhage. Peritoneum opened in usual manner after all bleeding was controlled.

As soon as the abdominal cavity was opened the tumor presented itself, which proved to be an enormously distended gall-bladder with exceedingly thin

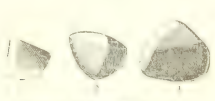
Fig. 1.

Gall-bladder, removed from [illegible] 11.

walls. After pushing the bowels aside and getting my hand under the liver, I detected a large stone firmly impacted in the cystic duct, completely obstructing it. All the gentlemen assisting me followed my example and each felt the stone plainly. The walls of the gall-bladder were so exceedingly thin that the greatest delicacy was necessary in handling it. Yet, unopened as it was, it promised such a good hold in handling it while detaching it from the liver, that I did not now aspirate it, as Langenbuch does, but first separated it completely from all sides. After this was done, by careful manipulation I succeeded in working the obstructing

stone from the cystic duct back into the gall-bladder. All ducts were now closely examined. They were free and unobstructed. I now ligated the cystic duct with carbolized silk, and punctured the base of the gall-bladder with the point of a knife, evacuating more than a pint of a transparent muco-serous liquid and a few small stones, the gall-bladder being meanwhile held outside of the abdomen. After it was emptied of its liquid contents, I divided it close to the ligature with the Paquelin cautery and removed it with all the stones it contained, 135 in number. The ligature was cut short and the stump,

FIG. 2.



Some of the stones of Case II.

after being dusted with iodoform, dropped. A few layers of Lister gauze, which had been stuffed into the abdominal wound to catch up any liquid that might escape, were removed; and after washing that part of the bowels and liver which had been exposed, with a 1:2000 corrosive sublimate solution, the whole wound was closed with deep and superficial silk sutures, iodoform freely dusted over it, and a large pad of absorbent cotton applied and held *in situ* by a binder tightly secured. No drainage tube was put in.

The patient reacted well. There was scarcely any shock, and aside from the usual ether vomiting, which was controlled by hypodermatic injections of morphia and cracked ice by the mouth, she was in every way comfortable. On the third day the temperature rose to 101° F., the highest point ever reached during her recovery. Her pulse never rose over 90. On the fifth day she was troubled by constipation, and her bowels were moved with a few doses of calomel. After this she had natural movements every day. There is nothing of special interest in her convalescence. On the eighth day I removed the dressing for the first time, and finding the whole wound healed by first intention removed all sutures and simply supported the abdomen with a binder. She sat up on the eleventh, and went out on the thirteenth day after the operation. Her appetite is good, bowels regular, and feces of natural color, she is free from all pain and has in every way fully recovered.

The points of greatest interest in these two rather analogous cases lay in the difference of the operative procedures, and in comparing their ultimate and immediate results with one another.

To be continued.

ALBUMOSE- AND PEPTONE-FEVER.

PRELIMINARY NOTE.

BY ISAAC OTT, M.D., AND CHARLES COLLMAR, M.D.,
OF EASTON, PA.

THE discovery by us that trypsin, when injected into the circulation causes fever (3½° F.), led us to investigate more minutely the action of this ferment.

Fairchild's trypsin was treated by saturating it with sulphate of magnesia, to remove any globulin that might be present, and the filtrate was heated after the method of Hofmeister to remove all the albumin, except the peptone. By this method we obtained a solution of peptone plus a saturated solution of sulphate of magnesia and a little acetate of sodium. To remove a greater part of the salts we submitted the solution to dialysis, and the solution coming through was evaporated to a small bulk. Alcohol was added, which precipitated the magnesium salt and the peptone, but the salt being heavier rapidly fell to the bottom of the test tube. The alcohol containing the insoluble peptones was rapidly decanted, evaporated to dryness, and the peptone dissolved in water.

The solution was then injected into the jugular, and a rise of temperature occurred. These experiments, as well as others by dialysis, demonstrated that trypsin caused fever, not through itself, but by a peptone. This led us to try other agents, and we found that Merck's meat peptone and papayotin also caused fever. In fact, the highest fever we have so far obtained has been by papayotin. These experiments led us to try the albumoses and peptones.

Through the kindness of Prof. Chittenden, of Yale College, we obtained albumoses and peptones. His name is a sufficient guarantee of their purity, as his researches upon these subjects are well known. When either proto-albumose or deutero-albumose, anti-peptone or ampho-peptone, were injected into the circulation, fever ensued, notwithstanding the dose was not over one-sixth of a grain. The effect of these bodies upon heat-dissipation and heat-production, how they act upon the inhibitory heat-centre discovered by one of us, will be detailed in the full report.

The large amount of albumoses and peptones poured into the system daily causes this subject to be one of great interest, for any deviation of the usual phenomena of absorption and assimilation might be fatal to the patient.

These experiments were performed on etherized rabbits, the number being twenty.

A NEW OPERATION FOR PROLAPSUS ANI.[1]

BY FREDERICK LANGE, M.D.,
OF NEW YORK.

THE patient whom I intended to present to you, but who has not appeared (probably being prevented by his professional duties as a detective), is not yet forty years of age, though he looks much older. For almost twenty years he had been suffering from prolapsus recti, with more or less incontinence. It seems that an inflammatory disease of the rectum (probably dysentery), accompanied with intense tenesmus, was the original cause. He has been operated upon a number of times after the usual methods (cauterization and excision of the mucous membrane), but apparently with only transient and partial relief.

[1] Read before the New York Surgical Society, Jan. 26, 1887.

After one operation, done by my colleague, Dr. Adler, he was improved for several years; altogether he had undergone five different operations, when, in October last, he was readmitted to the German Hospital. He suffered from incontinence as before. The anal ring was quite relaxed and wide open, and even with slight pressure the rectum was extruded. The patient assured me that the prolapse was at times worse than ever before, and, from Dr. Adler's statement, I conclude that formerly the rectum would protrude to the length of fully six inches.

Not taking into consideration cases of partial prolapse of the rectal walls, we must admit that our methods of treating prolapsus recti do not yield very encouraging results. I once, in preantiseptic days, assisted at the operation of amputating such an extensive prolapse, after a preliminary operation, the purpose of which was to cause an inflammatory adhesion of the peritoneal layers. The patient died several weeks later from septicæmia. The amputation was done, if I am not mistaken, by the galvanocaustic snare. In our present aseptic age, I believe that such an operation, or a similar one, would be much less dangerous, but the question is, Would the result be lasting? So long as the lower part of the gut is allowed to pass through a widened and relaxed muscular sheath, which is formed by the levator ani and the sphincters, and the lowest portion of the rectum itself remains wide, there is always, I think, a strong probability of recurrence. I therefore, in my method of operating, tried to meet both indications, to narrow the rectum as high up as possible, and to fix around it a contracted muscular ring.

Anatomical and clinical observations lead me to infer that the levator ani takes an important part in the closure of the rectum. If one places the tip of his finger upon the anus, and then tries to make that muscular effort by which the passage of feces is prevented, it will be found that the anal orifice is not only lifted, but also drawn slightly forward against the perineum. This, I presume, is due to the action of those fibres of the levator ani, which, in passing behind the rectum and uniting with those of the opposite side, form a strong muscular arch, which in contracting must necessarily exert a pressure against the posterior wall of the gut, and in this way cause closure of the same.

I operated in the following manner: The patient was fixed on the table in the knee-elbow position, a thick cushion placed between his knees and under the lower part of his thorax and the upper part of his abdomen, giving a sufficient support; his legs were tied to the table, and his head rested sideways on a pillow. I have lately performed almost all of my rectal operations with the patient in this position, and I cannot recommend it enough. The hemorrhage is decidedly diminished, the parts are more accessible, and the principal vessels can nearly all be secured before they are divided. An incision was carried from the lower part of the sacrum down to the anus, until the posterior wall of the rectum was reached. I then removed the coccyx, for two reasons—first, I wished to narrow the gut as high up as possible, and, secondly, I thought that the proposed action of the levator ani might thus become less impeded.

The lumen of the rectum was narrowed in such a way that buried étage-sutures of iodoform catgut were introduced, which did not perforate the entire thickness of the gut, the first row being inserted near the middle line and forming a fold in the posterior wall which protruded into the rectum. In this way the more lateral portions of the gut, so far as it could be done without causing too much tension, were brought into apposition. Then the surfaces of the levator ani and sphincter externus, which had been dissected back in order to lay bare the posterior wall of the rectum, and next their cut surfaces were united by similar sutures. In order to secure a more lasting union, several buried sutures of silkworm-gut were also inserted into this muscular crest. Finally, a few sutures in the integument were introduced and the cavity corresponding to the removed coccyx was left open and loosely packed with iodoform-gauze.

The healing process proceeded without any special disturbance; everywhere the sutured parts united by first intention, and only from that portion of the wound which had been left open did a slight secretion take place. The patient's control over his bowels began to be manifest after the first few weeks, and never after the operation did the prolapse recur. Gradually the muscular closure became more and more complete, and now, if you insert your finger into the rectum, you will be able to make out a very strong voluntary action of the muscles.

I observe in this case the greater depth of the rima ani, and the fact that it is drawn inward by the action of the levator. I have tried, in a case of extirpation of the rectum for melanotic tumor, to secure muscular closure by uniting the levator ani. The result is not absolutely perfect, but the patient, a woman of about forty years, has more control over her bowels than these patients usually have. Only about three and one-half inches of the gut, including the sphincter, were removed in this case. Of course, in more extensive operations, where the gut cannot be sufficiently pulled downward, this plan cannot be executed.

AN IMPROVEMENT IN THE METHOD OF PREPARING BLOOD SERUM FOR USE IN BACTERIOLOGY.

By A. C. ABBOTT, M.D.,

STUDENT IN PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

To those who employ blood serum as a culture medium in bacteriological research, a short note upon an improvement in the method of collecting and preserving it may be of service.

The evaporation of water from serum when coagulated in test-tubes, ready for use, is so rapid as to render its preservation in this form, in large quantities, impracticable. Hitherto it has been customary to collect fresh serum for each supply of tubes that we required; and as only a small number of tubes could, in this way, be kept in a condition for use,

for reasons stated above, this procedure necessitated no inconsiderable loss of time. It is to obviate this loss of time that I have endeavored to devise a method by which serum might be kept in the laboratory in a fluid state, sterilized and ready for use when required.

The method pursued, in short, is as follows: One or two thoroughly cleansed museum or fruit jars, having covers that hermetically seal them, are filled with blood as it flows from the large vessels of the animal's neck. They are then immediately covered and set aside for fifteen or twenty minutes until clotting has commenced, when a clean glass rod is passed around the circumference of the upper surface of the mass, in order to break up any adhesions that may have formed between the blood and the walls of the jar, thus preventing the watery portions of the blood from occupying the upper part of the vessel when the clot is complete.

They are then placed in a refrigerator (the laboratory refrigerator is safer than leaving them in the ice chest at the slaughter house) at a temperature sufficiently low to prevent the development of the organisms that must have gained access during exposure, and yet not so low as to interfere with perfect coagulation. At the end of twenty-four to thirty-six hours a very considerable amount of serum will have separated. This is then pipetted off into thoroughly cleansed glass or wool-stoppered cylinders. The serum at this stage may be of a clear straw color or may be reddish from the admixture of red blood-corpuscles, the amount of color depending upon the care with which it has been transported from place to place. These cylinders are then *packed in ice* for at least three days, when all of the suspended coloring particles will have precipitated to the bottom, leaving a clear transparent supernatant fluid.

The clear portion is then carefully drawn off by means of a sterilized pipette into wool-stoppered 100 c. c. flasks that have been sterilized by dry heat at a temperature of 150° C. for at least an hour. Each flask should contain from 60 c. c. to 75 c. c. of the serum.

Sterilization by the fractional method is then begun and is continued through six successive days for an hour each day. In sterilizing after this method the temperature within the chamber should at no time during the hour be higher than 64° C., and, if possible, should not fall below 58° C.; a rise in temperature much above 64° C. causing cloudiness, and a fall to any extent below 58° C. not being sufficient to kill the organisms. At the end of six days the flasks containing the serum are sterile and may be kept indefinitely. By following this plan we not only have at hand a stock of liquid serum, but a serum that has stood sufficiently long to have become, by the precipitation of its solid particles, almost colorless and clear.

Larger flasks than are above advised might be employed, but as we rarely prepare more than fifteen or twenty test-tubes at a time, a flask containing more than 100 c. c. of serum would of necessity require sterilization after each opening, and it is to obviate this that the whole amount is distributed through smaller flasks that may, with but little loss of serum, be discarded after once having been exposed.

In the different steps of this process much care is necessary in order to limit the amount of bacterial contamination to the minimum, and the stage at which there is liable to be the greatest contamination is in collecting the blood as it flows from the large vessels in the animal's neck. The skin and hair about the wound contain countless organisms and were the blood allowed to flow over these surfaces before collecting it, its complete sterilization would be a matter of some doubt. To exclude this, the animal, before being killed, should be thoroughly secured and then suspended by the hind quarters to the ceiling above, so that when the throat is cut the head may be freely drawn back and allow a vertical uninterrupted flow of blood from the vessels into the receptacle.

The importance of blood serum as a culture medium is seen in the fact that it presents the only artificially prepared substance upon which some of the most interesting and important of the pathogenic organisms will grow; but as its preparation has always involved quite a loss of time, it is, in a measure, discarded for some of the more conveniently prepared media.

We have pursued the above plan during the past twelve months, and it has proven satisfactory in every respect. There are now in the laboratory a number of flasks of liquid serum that were prepared in this way ten months ago, and, except that they are clearer, they differ in no respect from serum freshly prepared.

MEDICAL PROGRESS.

DIFFERENT METHODS OF TREATING CERVICAL CATARRH.—DR. L'VOFF, of Kazan, has reported in the *Meditsinskoe Obozrenie* a number of observations made on the comparative value of different methods of treating catarrh of the cervix uteri. The total number of cases was eighty-two. Of these thirty-six were treated by mechanical scraping of the mucous membrane, eighteen by means of powerful caustic applications, and twenty-eight with weak caustics. The method of applying the weak caustic was, after washing out the vagina with warm water or a solution of boracic acid, to swab the cervical canal with tincture of iodine or with a 10 per cent. solution of chromic acid. This was done once a week, plugs soaked in glycerine of tannin being also used every other day. The strong caustic application consisted of a bougie made of sulphate of zinc and alum fused together. This was allowed to remain in the canal till it had all dissolved, which took place usually in one or two hours. Afterward the mucous membrane presented a white appearance, due to the eschar. This fell off in five or six days, during which time warm vaginal douches were administered and plugs of glycerine and iodoform inserted every alternate day. In the cases treated by scarification an iodoform glycerine plug was left in for twenty-four hours, and the patient was then sent home. The results of these different methods of treatment were that the mild caustics

ultimately effected a cure, but required at least two months to do so; while the severer methods—that is to say, the fused zinc and alum and the scarification—produced a permanent cure in about a fortnight. The author adds that no unpleasant symptoms were caused by either the caustics or the scarification in any of the eighty-two cases.—*Lancet*, Jan. 22, 1887.

A Successful Treatment of Sciatica.—Dr. John T. Metcalfe gives the following prescription, which he has used with marked success in sciatica:

℞.—Tinct. aconit. radicis,
Tinct. colchici sem.,
Tinct. belladonnæ . equal parts.—M.
Sig.—Six drops every six hours until relieved.

Dr. Metcalfe uses tablet-triturates, each of which contains three drops of the following mixture as the most convenient form in which to prescribe its ingredients:

Tinct. aconit. rad.,
Tinct. colchici sem.,
Tinct. belladonnæ,
Tinct. actææ racemosæ, equal parts by volume.

One of these tablets is given every four, six, or eight hours, as may be needed.

Marked beneficial effects have followed its use in three days; and in neuralgia of the axillary and brachial nerves it has proved of great value.—*Boston Medical and Surgical Journal*, January 27, 1887.

Determination of Sex.—Kisch, of Prague, has reviewed former theories on this subject, and found in 1972 births, 1023 males and 949 females; his results do not agree entirely with those of Hofacker and Sadler.

Kisch found when the man was older than the woman from 1 to 5 years, 294 male to 283 female children; when the disparity in ages was from 6 to 10 years, 327 males to 306 females; 11 to 15 years, 190 to 167; 16 years or more in difference of ages between man and wife showed 138 males to 113 females; when ages were equal, 34 males to 42 females were born.

When the woman was older than the man, 40 males and 38 females were born. When the man was older than the woman, and the woman's age was between 15 and 19, 280 male to 287 female children were produced; when the mother's age was between 20 and 25, 595 males and 513 females; when between 26 and 32, 74 males and 69 females. The observer concludes that when the man is at least 10 years older than the woman, and the woman is at the age of greatest reproductive activity (20 to 25), more male children than female are born. When man and woman are of equal age, female children predominate. Women older than their husbands produce more male children, but not an excess.—*Centralblatt für Gynäkologie*, January 22, 1887.

Antiseptic Operation for Cataract.—Panas describes the following as his method of antisepsis in this operation:

He employs the biniodide of mercury in the following proportions:

Hydrarg. iodidi rubri . . .	gr. ¼.
Spirit. rectificat. (90°) . . .	℥v.
Aquæ destill.	quart 1.

The field of operation is irrigated with this fluid by means of a small instrument resembling an ordinary medicine dropper. The corneal flap is made of the greatest possible regularity and of considerable size.

The toilet of the pupillary field is made as complete as possible; fragments of the cortex, blood, pigment, air bubbles are carefully removed. The pupil is made to contract completely, and the iris is wholly reduced before the eye is closed. Several drops of eserine are instilled into the eye, and a vaseline ointment of this drug is introduced at the conjunctival cul-de-sac.

The eyes are gently closed, and each is covered with linen anointed with

Hydrarg. benzoat.	grs. 23.
Cerati	℥iijss.

Carbolized cotton, in light compresses, is applied over this.

The dressing is renewed every twenty-four hours, taking care to open the eye as little as possible for three or four days.—*Les Nouveaux Remèdes*, January 24, 1887.

Unusual Site of a Hydatid Cyst.—A case of hydatid of the scrotum came under the care of Mr. Philip E. Muskett in the Sydney Hospital during the course of last summer, and as this is an example of a very rare condition, a brief note will be of interest. The patient, aged twenty-five, had been in Australia since he was three years old, and in a sheep district where the water was very bad for four years before the swelling appeared; this was first noticed eight years before he came under treatment. During that time it had been tapped twice, and, on the second occasion, also injected with iodine. When admitted to the hospital "there was an intra-scrotal tumor, about the size of a large emu egg, on the right side. It was smooth in outline, and its general contour nearly oval. The tumor was tense and dull on percussion, but gave to the fingers on palpation the sensation of fluid within. There was no impulse on coughing, and it was irreducible. The position of the testicle at its posterior part was made out by the presence of testicular sensation. The cord could not be clearly defined at the upper portion of the swelling. Light was transmitted by the ordinary manner of procedure, and, finally, the history had been that of an eight years' growth; painless, except from its mere weight." The cyst was tapped on the day following admission, and about an ounce of "serous-looking fluid" of pale yellowish tinge evacuated. Suppuration followed this tapping, and thirteen days later about six ounces of purulent fluid were drawn off. After this pus drained away from the puncture for eleven days, then a hydatid sac partly forced its way out, and was partly extracted through this opening. The sac was grayish in color, translucent, and elastic, and in its sunken condition would about fill an egg-cup. The swelling gradually subsided, the sinus closed, and the patient left cured.—*Lancet*, Jan. 29, 1887.

Use of Salol.—Kleefeld, of Görlitz, reports from his clinic the following results obtained by the use of this drug. His use extended over a period of three months, and in thirty-five cases of rheumatism and varying forms of neuralgia he obtained the best results.

There followed no ill after-effects from its administration; ringing in the ears occurred infrequently and was not severe.

It is tasteless, odorless; is taken willingly.

Its price is low.

Large doses, thirty grains, three times daily, were rarely given; as good effects were obtained from doses of fifteen grains three times daily. It bears very favorable comparison with antipyrin and salicylate of soda in the diseases mentioned.—*Berliner klinische Wochenschrift*, January 24, 1887.

MORTALITY AMONG THE HABITUAL USERS OF ALCOHOL.—BAER, of Berlin, has compared the results obtained in England by the investigation of the mortality among those who dealt in alcoholic drinks and who used them, with statistics obtained in Prussia. Baer's information was obtained from official returns, gathered among brewers, distillers, beer, brandy, and wine handlers, keepers of inns and restaurants, waiters, bottlers, etc.

14,295 males, of whom 13,528 were more than twenty-five years old, were included in the inquiry. His results are as follows:

The years of life to be expected by persons of various ages who were not handlers of alcohol were compared with the portion of life remaining to those who used and handled alcohol constantly:

Non-handlers of alcohol aged

From 25	had before them	. .	32.08 years.
" 35	" " "	. .	25.42 "
" 45	" " "	. .	19.12 "
" 55	" " "	. .	14.13 "
" 65	" " "	. .	9.72 "

Those who had constantly to do with alcohol had in the future—

From 25	years of age	. .	26.22 years.
" 35	" "	. .	20.41 "
" 45	" "	. .	15.10 "
" 55	" "	. .	11.16 "
" 65	" "	. .	7.94 "

Causes of death among the constant users of alcohol and those not concerned with it were

	Of handlers of alcohol. Per cent.	Of others. Per cent.
Brain disease . .	11.77	14.43
Tuberculosis . .	30.36	11.57
Pneumonia and pleuritis	9.63	11.44
Heart disease . .	1.46	3.29
Kidney disease . .	1.40	2.11
Suicide	2.99	4.02
Cancer	2.49	8.20
Old age	22.49	7.95

In England 14 per cent. of deaths were caused indirectly by alcohol, 4 per cent. directly.

Baer calls the attention of those interested in hygiene to these statistics.—*Deutsche medicinische Wochenschrift*, January 27, 1887.

EFFECT OF IRON ON THE COMPOSITION OF MILK.—DR. MENDES DE LEON has made a number of researches and observations on the supposed effect of taking iron on the composition of the milk secreted. He finds that milk always contains a minute quantity of iron, which differs in different species of animals, cow's milk, for example, being richer in iron than human milk. He gave various preparations of iron to a healthy multipara, and analyzed the milk, but was unable to detect any increase in the iron it contained, so that it would appear that iron given to the mother does not act on the child by passing into its system, but that it may act by improving the general condition of the mother, and thus causing her to secrete better milk.—*British Medical Journal*, January 29, 1887.

THE ELASTIC LIGATURE FOR UTERINE FIBROIDS.—The removal of uterine fibroids by means of the elastic ligature having been recently adopted by Prof. Slavyanski in four cases, a paper has been published by one of his pupils, Dr. Zhabotinski, dealing mainly with the history of this method of operating. He has collected accounts of 216 cases, of which 151 are British (44 being Dr. Robert Lee's), 27 French, 20 German, 10 Russian, 5 American, and 3 Italian. Of these 18, or 8.3 per cent., proved fatal—8 from peritonitis, 3 from septicæmia, 3 from exhaustion, 1 from pleurisy and peritonitis, 1 from meningitis, 1 from tetanus, and 1 from an accidental disease. In 12 of these death occurred before the tumor came away, and in the remaining 6 after separation had taken place. The author thinks that the opinions of West and McClintock on the dangerous character of this method of procedure were formed on the results of too small a number of cases, and that as most of the published cases occurred in preantiseptic times, the danger with modern methods may be looked upon as very slight. The mode of procedure which Prof. Slavyanski adopted, and in which Dr. Zhabotinski's opinion is the best, is to cut away the tumor after the elastic ligature has been applied to the peduncle. This seems to have given the best results, even before the days of antiseptics. The main indications for the elastic ligature operation are a pedunculated condition of the tumor, an accessible situation, and a disposition to hemorrhage.—*Lancet*, Jan. 22, 1887.

A PRESCRIPTION FOR ACUTE BRONCHITIS.—MUIRHEAD, in the *Edinburgh Medical Journal* for January, 1887, gives the following as serviceable in the preëxudative period of acute bronchitis:

R.—Vini antimonialis	. . . 3iii.
Liquoris potassæ	. . . 3ij.
Liquoris ammoniæ acetat.	. . 3iij.
Syrupi aurantii	. . . . 3jss.
Aquam	. . . . ad. 3vi.—M.

Sig.—One tablespoonful in wineglassful of water every three hours.

ABSORPTION OF CORROSIVE SUBLIMATE BY THE SKIN.—DR. KOPFF states in the *Przeglad lekarski* that, having made seven experiments with careful analyses according to the methods of Schneider, Schriddle, and Lehman, with the view of determining the power of absorption possessed by the skin for corrosive sublimate, he has found that healthy skin can absorb small quantities from aqueous solutions containing from one to two per cent. of the salt. The quantity absorbed, which, however, is never large, seems to depend mainly on the degree of concentration of the solution. The chloride of mercury is also invariably excreted very soon after it has been absorbed.—*Lancet*, Jan. 8, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 19, 1887.

LITHOLAPAXY IN MALE CHILDREN.

In all of our treatises and text-books on surgery it is dogmatically asserted that crushing a stone in the bladder of impubic male subjects, with or without rapid evacuation of the fragments, is a bad operation. This statement is based, first, upon the assumed undeveloped condition of the genito-urinary organs, the narrowness of the urethra, and the small size and sensitiveness of the bladder; and, secondly, upon the old statistics of lithotrity—that is to say, the operation which requires more than one sitting for its accomplishment—derived from the Moscow Clinic and the Children's Hospital of Paris, which show 12 deaths in 83 cases, or 1 in 7, as against 1028 cases of lateral lithotomy, collated by Thompson in the same class of patients, with 68 deaths, or 1 in 15. From these facts, or assumed facts, lateral lithotomy is held to be safer in children than crushing; but, as in other surgical procedures, as, for example, abdominal surgery, the question arises whether tradition, fortified by groundless objections, badly adapted instruments, and insufficient experience, has not stood in the way of progress in this direction, and condemned many children to a dangerous and, as a rule, unjustifiable cutting operation, namely, epicystotomy, the present fashionable craze, which might have been relieved by properly and skilfully performed rapid crushing, with evacuation of the fragments?

The most satisfactory answer to this question is to be found in a series of papers on "Litholapaxy in Male Children" contributed to *The Lancet* for December 4, 11, 18, and 25, 1886, by Surgeon-Major Keegan, of Indore, Central India, which deserves the careful study of the practical surgeon. In this contribution the author gives a table of 58 cases, of which all save eleven are personal, of Bigelow's operation in children whose ages ranged from twenty-one months to fourteen years, with only 1 death, and that case should have been reserved for lithotomy, the stone having formed upon a "tilli" stalk. An analysis of the table indicates that the age of 27 patients varied from less than two to five years inclusive, and that the fatal case occurred in this class; that 24 were between six and ten years inclusive; and that 7 ranged between eleven and fourteen inclusive. The time occupied by the operation varied between four minutes for a uric acid stone which weighed seven grains, and three hours for an oxalate of lime calculus which weighed seven hundred grains, and required for its crushing not less than twenty-six insertions of the lithotrite. Of 56 cases in which the weight of the débris is noted, it was less than fifty grains in 26, from fifty to a hundred grains in 9, from one hundred to two hundred grains in 11, from two hundred to three hundred grains in 6, from three hundred to four hundred grains in 3, and seven hundred grains in 1. More than two thirds of the calculi were composed of uric acid or oxalate of lime.

From this presentation of the facts derived from a study of the table, we do not wonder that Keegan asserts that the only cases of stone in male children which he reserves for lateral lithotomy are those in which litholapaxy—not lithotrity, be it marked—is contraindicated by the existence of a very narrow urethra, or the presence of an abnormally large or hard calculus. The facts and figures support his views, and they also prove that the objections concerning the condition of the genito-urinary organs in impubic subjects are not valid. The undeveloped state of the prostate is an advantage; the bladders of boys suffering from a stone are, as a rule, healthy, and relatively capacious; those of subjects two, three, or four years old, being roomy enough to permit the efficient working of a suitable lithotrite and evacuating tube. The objection that the organ is extremely sensitive may be disregarded, as the operation is always performed under the influence of an anæsthetic. It is, moreover, not true that the calibre of the urethra is small, a fact of which all lithotomists are aware, and which leads them to use a relatively large staff. Should the meatus be small, an incision discloses that a lithotrite of considerable size will readily pass into the bladder, and it is due to the fact that the meatus was seldom divided in the old and dangerous operation of crushing in boys that the true calibre of the urethra was not discovered. A still further study of the table shows that from twenty-one months to thirty-four months a lithotrite, No. 7 of the English scale, was admitted and manipulated with ease; that during the

third and fourth years, No. 8 was generally employed; and at five years, that No. 10 was resorted to in five-eighths of all cases. Without going into further details, it may be said that lithotrites, Nos. 8 and 10, were most frequently used, and that with a No. 8 lithotrite and a No. 8 evacuating catheter, mulberry calculi, weighing between two and three hundred grains, were disposed of in an hour's time.

Given a light hand and gentle and careful manipulation, litholapaxy in boys differs from that operation in adults only in the size and construction of the instruments used. The size of the lithotrite should correspond with that of the urethra, so that the surgeon should be provided with a set running from No. 6 to No. 10 of the English scale, the meatus being divided as a preliminary measure when it is small. The only perfectly safe form is one with the female blade completely fenestrated, which cannot become clogged with débris, a dangerous complication from the liability of wounding the urethra by sharp fragments. The evacuating catheter should be as short as possible, and be fitted with a stylet to dislodge any tightly wedged fragment which does not yield to the brisk working of the aspirator. Under all circumstances, it will be wise to pass the stylet before withdrawing the catheter from the bladder. It goes without saying that on account of the comparatively small size of the evacuating tube the stone should be pulverized, and that the surgeon should not be in a hurry to finish the operation.

The cases tabulated by Keegan were not selected, but taken as they came, some being feeble, and others suffering from chronic enlargement of the spleen from chronic malaria. The average stay of the patients in the hospital was seven days as against seventeen for lateral lithotomy, and many of them were practically well the day following the operation.

Litholapaxy in male children is certainly not to be undertaken by a novice. As in the operation in the adult, it requires skill, dexterity, patience, and judgment, and the surgeon who has had some successful experience with it in the adult is, with the aid of suitable instruments, more than justified, in the face of the facts which we have presented, in resorting to it.

It is well known that lateral lithotomy in impubic subjects is followed by most satisfactory results, the general mortality being only about 1 in 17. In the Norfolk and Norwich Hospital, 1 patient in every 15½ perished; in the St. Waldimir H spital, of Moscow, 1 in 16⅓ succumbed, while the 72 cases of S. D. Gross show only 2 deaths, or 1 in 35. Turning to India, the results are far more striking. Thus, Rai Ram Naran Dass, of Calcutta, lost 1 child in every 27⅓, while Freyer cut 143 boys without a single death, a success as brilliant as it is unequalled. If the operations done in India alone be compared, the 225 lateral lithotomies of Dass and Freyer afford only 3 deaths, or 1 in 75, as against 1 in 58 for litholapaxy.

From the foregoing data it may be asked, Why practise, as advised by Keegan, a comparatively untried operation in a class of subjects in which lateral lithotomy affords such satisfactory results? At the present time, the figures are on the side of the cutting operation, and we ourselves hold that it will be the operation for children until further experience demonstrates the comparative safety of rapid crushing with evacuation of the fragments. In the meanwhile, the unlooked-for success attained by Keegan demands that surgeons who have had experience with crushing in adults should resort to it in children. If a cutting operation, with its attendant risks from wound complications, can be replaced by a procedure which brings about a more rapid cure and does away with suffering on the part of the patient and personal anxiety and inconvenience on the part of the surgeon, it certainly is the operation which should be selected when it is not absolutely contraindicated.

The recent impetus given to suprapubic lithotomy, especially by German and French surgeons, who appear to be remarkably unsuccessful with perineal lithotomy, has led to its great abuse when applied to young subjects. Instead of limiting the method to large and encysted calculi, many operators other than those who enjoy few opportunities of cutting for stone have resorted to it for concretions of such small size that they could readily and safely have been removed by perineal cystotomy. The procedure itself is an easy one, and the risk from hemorrhage is very slight; but its results continue to be so very bad that it is time to cry a halt. Indeed, since its revival, additional experience seems to show that it ought to be utterly relinquished, except under the conditions to which we have adverted.

This is not a harsh criticism. Thus, of 133 examples of epicystotomy in impubic subjects collated by Dulles, up to 1875, 21 per cent. died. The statistics of Gross, of Nancy, brought up to a few months ago, and including the cases treated by improved antiseptic methods, comprise 307 cases, with a mortality of 21.62 per cent. Hence, the rate of death is greater by 7 per cent. than from the old operation of crushing. Schmitz, of St. Petersburg, records, in Langenbeck's *Archiv*, Bd. xxiii. Heft 2, 1886, 41 examples of the high operation, with 15 deaths, or a mortality of 36.5 per cent. Of the 18 operations done in preantiseptic days, 10, or 55 per cent., perished; while of the 23 performed under antiseptic precautions, 5, or 21.73 per cent., succumbed. The latter figures show a remarkable agreement with those of Dulles and Gross, and, with Schmitz, we can affirm that the improved methods of treating wounds have

not diminished the death-rate for the high operation in boys. Hence, the present indiscriminate resort to epicystotomy in young males cannot be too strongly condemned.

In the present state of our knowledge lateral lithotomy may be said, without fear of contradiction, to be the operation for boys of all ages, although it may properly give way to the still safer median method in lads after the seventh year in whom the stone has not a larger circumference than rather more than two inches. At an earlier age the space is too small to remove any but a small concretion without much bruising. When a calculus is encysted, or when its bulk is too large to hope for its easy extraction through a perineal wound, epicystotomy is eminently proper, care being taken to use strict antiseptic precautions, and to suture the bladder. In the meanwhile we trust that the surgeons of this country and of Europe, who are known to deal largely with cases of urinary calculi, may be induced to furnish themselves with the proper instruments, and test the merits of Keegan's conclusions. If further experience proves that litholapaxy constitutes the safest and most satisfactory mode of ridding a child of a stone, it ought to replace lithotomy just as it is doing in the adult in suitable cases.

THE TREATMENT OF LABOR COMPLICATED BY A FLAT PELVIS.

The proper management of simple vertex presentations, when the progress of labor is retarded by a diminished conjugate diameter, is a subject that must, at some time, have engaged the attention of all practical obstetricians. An expression of opinion will, therefore, be welcomed from Winter, Schröder's assistant in Berlin, whose position insures him a vast experience, not only in the Frauenklinik itself, but also in the immense outdoor service connected with it.

As a result of his experience, and after a study of the statistics of labor complicated by a flat pelvis, Winter arrives at the following conclusions: That, in primiparæ, as the abdominal muscles are tense, powerful, and capable of giving efficient aid to the contractions of the uterus, as the child is not so likely to be as large as in subsequent labors, and as the lower uterine segment is not so easily stretched to a dangerous degree of attenuation, the expectant treatment will be found, in the majority of cases, to give the best results; operative interference being resorted to, as a rule, only after the head has become engaged in the superior strait, when the labor may be terminated by the application of the forceps. In multiparæ, on the other hand, as the child is apt to be larger than in first labors, as the abdominal muscles are relaxed and cannot be depended upon to aid efficiently the expulsive efforts of the uterus, and as the lower uterine segment may soon become excessively stretched, the early performance of version will often avert the danger of a ruptured uterus, or the formation of fistulæ, the result of prolonged pressure upon the maternal soft parts.

Winter thus occupies middle ground between the views of Schröder and Winckel, the former advocating early version in cases of flat pelvis when the engagement of the head in the superior strait is delayed, although there is nothing in the general condition of the mother or child that demands operative interference; the latter, on the contrary, advising an expectant treatment as long as the general condition of the mother and child remains good. The reasons, more in detail, that influenced Winter in forming the opinions that he holds, and the statistics of labor in multiparæ and primiparæ, treated actively and expectantly, may be found in the last number of the *Zeitschrift für Geburtshülfe und Gynäkologie*.

BIRTH-MARKS AS EVIDENCE

A young woman in the ninth month of pregnancy lately appeared before a Mercer County, Pa., Justice of the Peace, and swore out a warrant for the arrest of a man on charge of assault, alleging that he had choked her, and twisted her left wrist, almost dislocating it. There were no witnesses, and the man's discharge was confidently expected. At the trial, which took place some weeks after the birth of the baby, the lawyer for the defence called for acquittal on the ground of lack of evidence, but the prosecution asked that the baby be admitted in evidence. The jury was then shown the marks of four fingers and a thumb on the neck of the infant, and a left wrist twisted out of shape and swollen, as if it had been suddenly wrenched. These birth-marks corresponded exactly with the injuries which the woman swore to having received a month before the baby's birth. It is stated that the prisoner was convicted.

Without doubt there are instances in which maternal impressions have influenced the physical condition of the fœtus, even so far as to induce local tissue changes. Such cases are, however, extremely rare, and for one genuine there are fifty spurious examples. On general principles we should say the judge should not have admitted the baby as testimony, and certainly no man should be convicted on such trashy evidence as is afforded by ordinary birth-marks.

PROTECTIVE INOCULATION AGAINST RABIES.

Since writing the editorial note in The News of last week, referring to Ernst's work, the full text of von Frisch's latest communication has come to hand in the *Centralblatt f. Bacteriologie und Para-*

sitenkunde, No. 3, 1887. Several of his conclusions are opposed to those of Pasteur. Thus, he finds that animals inoculated with the virus of progressive intensity — desiccated cords of from fifteen to one day—do not resist infection with the fresh virus of street rabies. With few exceptions, animals submitted to the preventive treatment after subcutaneous injection with street rabies, died of the disease even when the incubation was prolonged to thirty-four days. Von Frisch thinks that more work must yet be done before we can with certainty adopt a preventive inoculation in cases of hydrophobia in man. From the fact that the more intense method of protective inoculation introduced recently by Pasteur, will itself produce the disease in animals, there is a danger that by this means the disease may be communicated to man. We trust that the experiments so favorably begun at Harvard may be continued with a view of settling these disputed points.

DISINFECTION OF THE HANDS.

Referring to the fact that after autopsies in certain cases, such as puerperal peritonitis and typhoid fever, the fingers remain impregnated for hours with a fetid odor, of which they cannot be deprived by repeated washing, Duclos states, in the *Revue de Thérapeutique*, that this can be instantaneously removed by the use of the potassic permanganate and the sodic bisulphite. The permanganate may be employed in the proportion of 5 to 1000, or 5 to 100, and the commercial solution of the bisulphite diluted with five parts of water. The method advised is as follows: First thoroughly wash the hands with soap and water; then in the permanganate solution, the time varying according to its strength, two minutes being sufficient if the solution be concentrated; the hands are then placed in the solution of the bisulphite, and they become at once white, the discoloration caused by the permanganate instantly disappearing.

Duclos claims that this method not only completely removes the repulsive odor, but also thoroughly disinfects the hands, and that it will prove useful to both surgeons and accoucheurs. So far as the latter class is concerned, they have no business with post-mortem examinations of infectious cases; and doubtless should the plan advised by Duclos be employed by them they ought to add to it the careful and thorough use of the nail-brush, to be followed by dipping the hands in a solution of corrosive sublimate 1 to 1000.

A meeting was held in Brooklyn, on February 7, by the physicians of Kings County who are in sympathy with the "National Code of Ethics," to consider the propriety of organizing a new society. The necessary committees were appointed and action taken which will in the near future effect the establishment of a new county association.

An effort has been made recently by the Kings County Medical Society to increase their building fund now in bank, amounting to $4000. The members have thus far subscribed about $6000, and they now look forward to the purchase of a property suitable for their meetings and for library purposes.

The Johns Hopkins Hospital had expended upon its buildings, during the past year, $112,000, and during the current year $150,000 more is available, and this sum will almost complete the work on the buildings and grounds. The site is a high elevation, commanding a view of the entire city and harbor of Baltimore. It is terraced and ornamented with plants and trees. It is reported that the hospital will be completed and opened in October, 1888, with a capacity of three hundred or more beds. All expenses on account of construction and equipment have been defrayed from the income, which annually yields about $150,000, and the original endowment remains intact.

Dr. J. C. Shaw recently resigned his position as Superintendent of the Kings County, N. Y., Asylum, resuming practice as a neurologist in Brooklyn. The vacancy has just been filled by the appointment, by the Charities' Commissioners, of Dr. John A. Arnold, the County Hospital physician, to be the general superintendent of the asylum and of the new "county farm" growing up at St. Johnland. He will be assisted by Dr. G. N. Ferris, who will reside at the asylum, and by Dr. D. A. Harrison at the St. Johnland farm.

A case of chloroform death occurred in this city last week in the practice of Dr. Wm. H. Pancoast. The anæsthetic was administered to a man aged thirty for the purpose of having adhesions of the finger tendons of the hand broken up. The usual remedies were applied without avail. The autopsy revealed the kidneys much diseased and an unusually fatty liver and heart, and a thin right ventricle.

Professor Billroth has been recently made a peer of the Austrian realm. Two members of the medical faculty of Vienna are now peers, Brücke and Billroth.

The collections for the Hospital Saturday and Sunday Association fund, in Brooklyn, have this year amounted to $6227.48, an increase, as com-

pared with those of the year previous, of $595.14. This charity has just closed its fifth year, its first appeal having been made in 1882.

REVIEWS.

THE SCIENCE AND ART OF OBSTETRICS. By THEOPHILUS PARVIN, M.D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia. 8vo. pp. 701. Philadelphia: Lea Brothers & Co., 1886.

WHILE, in these days of many books, the literature of many departments of knowledge is overcrowded and a new volume should indeed show good reason for its existence, yet it cannot be said that there are too many medical writers in this country, or that those that we have are too prolific. Students of medicine, thereby meaning, in the widest sense of the term, those that are about to end their studies with their lives as well as beginners, will be glad to welcome Dr. Parvin's work on Obstetrics, from the mere fact that it adds another to the list of distinctively American medical books; but being read, the book will be welcomed for itself, for, compact in form yet scholarly and in many respects exhaustive, it may well serve as a text-book for the student, or as a book of reference for the busy practitioner.

There are several points, however, which the careful student will feel disposed to criticise. The great influence of French writers and of the French school upon the book is at once apparent, while the German authorities are comparatively neglected, which is unfortunate, for in medicine, as in many other respects, Germany has of late years surpassed France. Those obstetricians who are advanced students of pathology will regret that the fact that puerperal fever is nothing but pyæmia, septicæmia, erysipelas, scarlet fever, or diphtheria, these diseases occurring in the puerperal state, is not more sharply emphasized; that more definite information is not given about the four pus-producing micrococci of pyæmia, the vibrio and the production of a ptomaine in septicæmia, or the presence of the chain micrococcus of Fehleisen in certain cases of so-called puerperal fever.

The description of rupture of the uterus will prove perhaps the least satisfactory portion of the book. The statement that "the lesion may occur in any part of the organ, neck, body, fundus, or sides," stands in decided contrast with Schröder's assertion that "the tear is never found in the contracted muscular portion of the uterine body," and nothing whatever is said of the appearance of the contraction-ring, while the stretched walls of the lower uterine segment seem to be regarded, for the language is rather ambiguous, as the walls of the cervical canal.

On the whole, however, we believe the book will be a source of pleasure and profit to those who read it carefully. The obstetrical operations are particularly well described, and no uncertain note is sounded in regard to the importance of antiseptic precautions not only during such operations, but also in the general management of labor and the puerperal state.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, January 26, 1887.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. THOMAS S. K. MORTON read a paper on

ABDOMINAL SECTION FOR TRAUMATISM, WITH REPORTS OF FIVE CASES AND TABLES OF ALL RECORDED CASES.

The term "abdominal section for traumatism" is meant to include those cases where the operator deliberately opens the belly, or greatly enlarges an existent wound for the purpose of discovering intraperitoneal wounds, and, if they are present, repairing them as far as possible, together with more or less final cleansing of the peritoneal cavity. Such cases as those in which wounds of prolapsed viscera are simply repaired, and the parts returned to the abdominal cavity, are not included.

Dr. Morton has collated the records of fifty-seven cases of laparotomy for trauma, which include all the cases he has been able to find in the literature of the world. Of these, 36 died, and 21 recovered: mortality, 63 per cent. These 57 cases were done by 42 operators, viz., 23 United States operators did 35 operations, with 11 recoveries, and 24 deaths: mortality, 67 per cent. 9 English operators did 10 cases, of which 3 recovered, and 7 died: mortality, 70 per cent. 2 Australian operators did 2 operations, with 2 deaths. 2 French operators did 2 operations, with 2 deaths. 2 Russian operators did 2 operations, with 2 recoveries. 1 German and 1 Swiss, each did an operation, with success. 1 Italian operator did 2 operations, with 2 recoveries.

7 operations have been done in Philadelphia by 5 operators, with 2 recoveries and 5 deaths. 5 of these have been performed at the Pennsylvania Hospital by 3 operators, with 2 recoveries, and 3 deaths.

Of the 57 tabulated cases, 38 per cent. were for pistol- or rifle-shot wounds; 35 per cent. for stabs; 17 per cent. for ruptured bladder, and 10 per cent. for ruptured intestine. In every case which died after operation, lesions certain to cause death, if uninterfered with, were found. One case of penetrating wound was opened, in which no visceral injury was found; it recovered.

The indications for abdominal section for traumatism are in many cases very clear; in others, with only our present knowledge, exceedingly obscure. Taking up the consideration first of wounds, the operation is clearly indicated in every case in which penetration of the abdominal cavity is proven, and with fair surroundings it becomes one's duty to open the abdomen and search for wounds, for there are no omnipresent symptoms which invariably indicate intraperitoneal wounds, even when extensive. With reference to cases suitable for operation, besides gunshot wounds, stabs, etc., which have already been operated upon, he conceived that in the future many other traumatic conditions will be subject to interference by section, such as rupture of the stomach, gall-bladder, spleen, or kidney, ruptured bloodvessels, various hæmatoceles, etc.

Where there is a wound of the anterior wall of the abdomen, first prove perforation by cutting down to the peritoneum. That should be a sufficient warrant for

section. In wounds of the back some judgment must be exercised. In the majority of the cases recorded, and in nearly all the successful cases, the incision was median. In several instances, where section has been done for a special purpose, such as removing an injured spleen, the incision has been made on one side of the median line. In one case of stab wound which he saw, the original wound was enlarged and gave rise to great difficulty in the subsequent steps of the operation. One wound was overlooked in that case, which error was largely due to the position of the incision. The length of the abdominal wound is to be governed by the circumstances of the case. There is no harm in a long wound if it be properly treated. After opening the peritoneum, note carefully the abdominal contents. If we find feces, we are encouraged to prolong the search until the wound is found. If there is blood, we should look for the vessel injured. The search for wounds should be thorough and systematic. In most of the cases where wounds have been overlooked, it has resulted from not making a systematic examination. We should begin at the entrance of the œsophagus into the stomach, if it is possible to reach so high, go over the stomach and all the intestines, examine the mesentery, the rectum, and bladder, and look at the spleen. Unless this is done, wounds will sometimes be overlooked, and even with the utmost precaution they will sometimes escape detection. Only those who have seen these cases can imagine the difficulty experienced in finding such wounds, especially when the upper part of the transverse colon and the surrounding omentum are involved. If the intestines are much distended, it may be necessary to puncture them. It is important to remember that extravasation has followed such a puncture, and it should always be closed with a Lembert suture. If the vermiform appendix or an epiploic appendix is injured, it should be excised. In wounds of the intestine, it makes a difference whether the injury is the result of a gunshot or of a stab. Gunshot wounds are more apt to slough than knife wounds, and where many of the former are located close together, it has been found advisable to excise a portion of the gut including the numerous lesions. Probably a foot of the bowel may be excised without much disadvantage. Six or eight feet have been excised, but in this case the operation was followed by emaciation and death. In such a case it would probably be better to make several excisions. Perforations when found should be turned into the bowel by the suture of Lembert. Wounds of the large intestine and stomach are to be treated in the same way.

Where the ball has perforated the mesentery, the wound edges should be excised. This is the opinion of those who have done most operations. The opening is then brought together with stitches on both sides, or passing entirely through. If the omentum be badly injured, no harm will come from its excision. It may be ligated in various places and the whole cut off without injury. In a hernia case, he cut off what he supposed to be almost the whole omentum, and the man recovered perfectly. Where the spleen is wounded, the only method seems to be to excise the organ. This has been done, so far as he knew, twice. Wounds of the liver have been met with a number of times and all the cases have died. If the kidney is extensively wounded, its excision or complete drainage is indicated. If the ureter is divided, the only remedy is excision of the corresponding kidney. If the projectile has gone through the diaphragm, the same operation as in the case of the mesentery would be indicated, namely, excision of the edges and sutures. Of course, all bleeding vessels are to be tied. If this is impossible, the main trunk, even if this be the aorta, must be tied. Wounds of the uterus and appendages have not been dealt with, but would probably require excision.

Then there is another class of wounds entering the abdomen—that is, wounds through the vagina and rectum; for instance, a stab wound through the vagina. If we knew that it penetrated, abdominal section would be indicated. In all these cases contusions of the omentum and intestine frequently are found. In time, nearly all of these will slough and give rise to pus. In several cases death has been attributed to this cause. All severe contusions involving the mesentery or omentum should be excised. When they involve the intestine, the peritoneum should be united over them with Lembert sutures. The suture materials which he has seen used have been silk and catgut, and he thinks the latter preferable if fine and chromicized.

The sooner the operation is performed, the better are the chances of the patient. The cases in which the time is reported number forty-five. The average time after the injury for which operation was done, was eighteen and a half hours. The average time after the injury when the operation was begun in the successful cases was seven and three-quarters hours; the average in the fatal cases was twenty-three and one-quarter hours. These are significant facts.

It is always difficult to decide, in any given case, whether drainage should be employed or not. If there have been extravasation and numerous wounds, drainage seems to be indicated. Glass and rubber tubes have been used with apparently equal success and failure. He thought that tubes of glass or other hard material are to be preferred. Where there has been extravasation of the contents of the stomach or intestine, this is usually followed by great oozing of serum.

The final steps of the operation are irrigation and cleansing. Irrigation should be very large in quantity, and if the patient is suffering from shock, there is no better treatment than pouring hot water through the abdominal cavity. It probably acts directly upon the solar plexus. He has seen this used frequently with marked benefit. The patient will be in far better condition after the use of a gallon or more of water at a temperature of 100° to 110°, than before its application. It has occurred to him that in profound shock from other causes, it might be well to puncture the abdomen with some form of double canula and thus irrigate the abdominal cavity with large quantities of hot water. What shall be put in the solution used for irrigation? Several agents have been so used: Water, distilled water, boracic acid solution, mild solution of bichloride of mercury, and solution of carbolic acid. Carbolic acid should be expunged from the list. Bichloride of mercury, when employed, should be in very dilute solution—1 to 5000 or 10,000. Boracic acid was used in two successful cases in three per cent. solution in unlimited quantities. In four cases at the Pennsylvania Hospital the bichloride solution in the strength of 1 to 5000 and 1 to 10,000 was used, and

apparently without any bad effect. It was used in both of the successful cases there. Distilled water is very good, and especially in cases where extravasation has not occurred. Where there has been extravasation, purulent peritonitis set up, or it is not certain that all foreign matters have been removed, an antiseptic is indicated. Where we have a solution like that of boracic acid, possessing fair strength, with little danger of poisoning, it should be used. The parietal wound is closed and dressed in the usual manner.

One question in the after-treatment would arise in cases where a drainage-tube had not been left, and would be with reference to reopening the wound and draining where a large amount of serum was present. Each individual case must be decided for itself. The onset of violent peritonitis would be an indication for reopening the belly, irrigating and draining it.

The total number of cases of gunshot wounds recorded is 22. Of these, 5 recovered and 17 died, a mortality of 77 per cent. Of these 22, 18 were done in the United States; 4 recovered and 14 died, a mortality of 77 per cent. The foreign cases were 4 in number, with 1 recovery and 3 deaths, a mortality of 75 per cent. The first recorded case of gunshot wound treated by abdominal section is that of Dr. Kinloch, of North Carolina, in 1881. The first recovery was the case of Kocher, of Switzerland, in 1883. The first American recovery was a case operated on by Dr. Wm. T. Bull, of New York, in 1884. These 22 cases were done by 15 operators—11 American and 4 foreign. In Philadelphia there have been 2 cases of abdominal section for gunshot wound. One was done at the Pennsylvania Hospital two days since by Dr. Thomas G. Morton. In one case of gunshot wound a wound of the intestine was overlooked, with a fatal result. McKellar, of London, reports a case of two wounds of the lower portion of the sigmoid flexure in which it was impossible to introduce stitches. All that he could do was to throw a ligature around the wounds. The patient died, and fecal extravasation was found at the autopsy. In this case rectal distention by a colpeurynter might have been of some assistance, lifting the bowel up so that stitches could be inserted, for the openings were on the anterior wall. Such cases are, however, exceedingly difficult to remedy.

In all the cases of stab wounds, with the exception of one, the wound was produced by a knife. In that one instance, it was caused by a sharp splinter of wood. As we should expect, this table presents the most favorable showing. The total number of cases reported is 19. Of these, 12 recovered, and 7 died; a mortality of 36 per cent. These operations were done by 14 operators —10 American and 4 foreign. The 10 American operators did 15 operations, with 8 recoveries, and 7 deaths. The foreign operators did 4 operations, and all recovered. The first case on record is that of Kwiectuski, of Russia, April 15, 1883. The first American one is that of Dr. W. O. Roberts, operated on August 28, 1885. The first recovery was the case of Kwiectuski. The first American recovery was the case of Dr. Roberts. The credit of the first recovery properly belongs to Dr. Roberts, of the United States, for the Russian operator had a large wound already made, which he enlarged to a certain extent, and sought for the intestinal wounds. Dr. Roberts had but the small opening made by a penknife.

The total number of cases of ruptured bladder reported is 10, with 4 recoveries and 6 deaths, a mortality of 60 per cent. There were 9 operators—3 American and 7 foreign. The American operators performed 3 operations, with 1 recovery and 2 deaths. The foreign operators performed 7 operations, with 3 recoveries and 4 deaths. The first recorded case of abdominal section for ruptured bladder is that of Walters, of Pittsburg, in 1862. This case was also the first recovery. In Walters's case he diagnosticated rupture of the bladder, with infiltration of the peritoneum with blood and urine. He opened the abdomen, cleaned it out, and put in a drainage tube, but did not sew the bladder wound. The second case was that of Alfred Willits, of London, operated on June 12, 1876. This case died. The second American case was that of Dr. Bull, operated on October 27, 1884. This case also died. Two recoveries have recently been reported by MacCormac. Philadelphia has had one case, which was operated on by Dr. Joseph M. Fox, August 16, 1886, with a fatal issue.

The symptoms of ruptured bladder are more definite than those of most other cases. The condition of the bladder at the time when the injury is received is of some importance, but cannot always be ascertained. Shock is usually present, as in other cases. Pain in the hypogastrium, fruitless efforts at micturition, vomiting, hiccough, distention of the abdomen with fluid, the withdrawal of blood or bloody urine by the catheter, are all good indications. If there is no urine in the bladder, or none comes in, it is a fair sign. The catheter can sometimes be introduced to a great length, and occasionally the rent in the bladder wall may by this means be detected. The withdrawal of an enormous quantity of fluid is another indication. If warm water is injected, it may be felt by the patient in the loins and other locations. With the catheter in the bladder, the liquid sometimes ebbs up and down with the movements of respiration. Recently Dr. Weir, of New York, has suggested a test for ruptured bladder, which consists in injecting a certain amount of fluid and percussing over the region of the bladder. If a definite outline of percussion dulness is noted, it is a fair inference that the bladder is not ruptured.

It is important to determine whether the rupture is extra- or intra-peritoneal. Stephen Smith has shown, in a collection of 65 cases, that the peritoneum is injured in 80 per cent. of the cases. Max Bartles found, in an examination of 166 cases, that the rent was intraperitoneal in 98, and extraperitoneal in 54. In 84 cases of intraperitoneal rupture the rent was situated at the fundus in 40 cases; in front, near the fundus, in 9; posteriorly in 33; and at the side in 2 cases. In 50 cases of extraperitoneal rupture, the rent was at the neck in 19, anterior in 23, posterior in 2, and at the side in 6. In 15 of these cases there was fracture of the pelvis. In these cases, as a rule, the urine found in the peritoneum is healthy, and not decomposing. An interesting paper has been published by a Russian, giving the toxic effects of urine which has escaped into the peritoneal cavity.

The method of operating is an interesting one. Having determined upon interference by section whether the diagnosis be positive or not, a median incision should be made and enlarged to suit the convenience of the operator. The incision may at first be made down to the bladder, as for a suprapubic lithotomy. If

there is a wound in front, you may feel it if it enters the peritoneal cavity; but even this is fallacious. Having found the wound in the bladder, the first thing is to clean the peritoneal cavity. Next, it is necessary to get the bladder into a position to suture it. This has been, until recently, found one of the most difficult steps of the operation. To obviate this, distention of the rectum with a colpeurynter has been practised. More recently, as in the case of Fox, sutures have been introduced on either side, and may be combined with the use of the colpeurynter. MacCormac, who found considerable difficulty in bringing up the bladder, made a lateral incision on each side through the peritoneum. This liberated the bladder very greatly. These peritoneal wounds he stitched together in the usual way, but this might be improved upon by introducing the stitches as Dr. Emmet does when sewing up his relaxation incisions of the vagina or elsewhere—that is, by uniting the wound by stitches passed into its longitudinal diameter. It has been found that the cases in which the sutures penetrate all the coats of the bladder invariably terminate fatally. This must be borne in mind, and the sutures passed through only the serous and muscular coats. The bladder wound is to be brought together with Lembert sutures of silk or catgut.

The after-treatment brings up the question of drainage, which has been discussed. A catheter should be left in the bladder. Another important thing is to prove that the stitches effectually control the opening in the bladder. This is done by injecting some solution—better, a weak antiseptic solution—into the bladder. If there is any leakage, additional sutures should be introduced; or the first row of stitches, by a second set, turned in.

The total number of cases of rupture of the intestine reported is five, of which number none recovered. 1 operation was performed in America and 4 abroad—2 in Australia, 1 in France, and 1 in England. The first recorded case is that of F. H. Girdlestone, of Australia, February 14, 1883. The only American case recorded is that of Dr. E. A. Wagner, on August 2, 1886. One case fell, and pressed a truss down upon a descended hernia; one was thrown from a horse; two were kicked in the abdomen; and one was crushed by a horse. In five cases the small intestine was ruptured, and in one the colon was the part involved.

DR. NANCREDE desired to say a few words about his own case, which, he thinks, shows the important point, although he could not secure a post-mortem, that peritonitis is not the only thing we should dread. He saw the boy six hours after he had been shot. The wound was a little to the left and above the umbilicus. He vomited blood one hour and a half after admission, although the operation showed that both the anterior and posterior walls of the stomach had been perforated. He determined that the wound was a penetrating one, and made an incision in the median line, and he would warn any against enlarging the existing wound, if not in the median line. He found a wound of the anterior wall of the stomach, which he closed with fine silk, using a fine sewing-needle. Then he found a wound in the anterior wall of the duodenum, which he sutured. He next looked for and found a wound of the posterior wall of the stomach. A large ragged wound in the posterior wall of the duodenum was also discovered. Examination from the stomach down almost to the ilio-cæcal valve revealed no other wound. A careful toilet of the peritoneum was made and the wound closed. The boy did well for forty-eight hours, and never presented the least symptom of peritonitis. When peritonitis comes on suddenly there may be a profound condition of shock which will not admit of rise of temperature, rigidity of the abdominal muscles, flexion of the limbs upon the pelvis, pain, or any of the usual symptoms; but this is not the case in slowly developing peritonitis. The boy died on the third day with a series of convulsions, with a very high temperature. He believed that he died of sapræmia, due to the absorption of ptomaines. The cold water coil, which was used almost from the outset in both of the successful cases of Bull, of New York, was not used, and he thinks more opium was given than was wise.

We have long been taught to give opium in full doses in traumatic peritonitis, but he believes that many cases are killed by this treatment. When the initial symptoms are marked by collapse, low temperature, rapid, feeble pulse, and clammy skin, if you give large doses of opium simply to ward off the expected inflammation, you will probably kill the patient. If you give moderate doses of morphia with large doses of atropia, you will possibly rally the patient and carry him over the shock stage. He thinks that large doses of opium should not be given in peritonitis, unless guarded by atropia. It should be given by hypodermatic injection, for it is uncertain how much will be absorbed from the stomach. At the end of a peritonitis where, from the respiratory centres becoming involved and from interference with the action of the diaphragm by tympany, hypostatic congestion of the lungs is taking place, persistence in the use of large doses of opium will kill the patient. If the opium is reduced to a minimum and given with large doses of atropia, or atropia is alone exhibited, you will sometimes tide the patient over.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, January 2, 1889.

R. F. WEIR, M.D., IN THE CHAIR.

OPERATION FOR THE RELIEF OF CARCINOMA OF THE RECTUM.

DR. LANGE presented a patient, sixty-five years of age, with paralysis agitans, the result of prolonged submersion in icy water several years before. He entered the German Hospital in October, complaining of difficulty in defecation of four months' standing. On examination he was found to have adeno-carcinoma of the rectum, and the diseased portion was removed in the usual manner, four inches of the gut being excised. The wound healed well. There was some constriction a short distance from the anus, probably due to the contracted sphincter internus. He had control over his bowels until he reached the closet, but was unable to have a thorough evacuation, so that he was inclined to have another movement soon after. In this case no attempt was made to unite the ends of the *levatores ani*, and the patient was obliged to wear a supporter. In another patient the attempt had been made, and on introducing the finger into the rectum it was evident that there was some voluntary muscular action.

ACUTE OSTEOMYELITIS OF THE FEMUR AT AN EARLY AGE; SECONDARY NECROSIS IN LATER YEARS; NECROTOMY; PLASTIC OPERATION FOR CLOSURE OF A LARGE BONE-CAVITY IN THE LOWER PART OF THE FEMUR.

Dr. Lange presented a patient with the following history: The patient, whom you see before you, is forty-six years old, and is a native of northern Germany. When ten years old, he had, according to his statement, a serious and very painful affection of his right knee and thigh, which kept him in bed for one year. His physician had proposed amputation to him, but, through the wisdom and cleverness of a midwife, as he said, his limb was saved, and he was able to get up on crutches. A number of sinuses had opened, and for about eleven years suppuration persisted, but then ceased. The shape and shortening of the limb have always been the same since that acute disease as at present, and at no time had any surgical operation been done, nor had any bone come away spontaneously. Until about sixteen years ago (that is, about nine years) all remained healed. Then, however, sinuses formed again, and did not heal. I saw the patient about one year ago. He himself attributes this renewed suppuration to his having habitually a board on his knee, over which he used a heavy flat-iron, while working at his trade as a tailor.

There existed a profuse, offensive discharge from a fistulous opening near the external edge of the right patella, just above the condyle, at the bottom of which necrotic bone could be felt. The whole limb now presents an extreme deformity. There is bony ankylosis of the knee-joint at an angle of about 140 degrees. The femur is about eight inches shorter than that of the other side, and there is a distinct angular bend at a point between the middle and lower third of the femur.

Just about a year ago I performed necrotomy, by making an H-shaped incision, forming flaps, which included the periosteum, and removing the patella and the anterior portion of the lower third of the bone, so that, after the removal of the numerous sequestra which you see here, a shallow bone-cavity was formed, into which the soft parts were depressed and fixed by strong straight needles. The healing process took place very rapidly, so that after about four or five weeks the patient went home with a few granulating, superficial wounds, which finally healed under an ointment-dressing. About three months later a fistula formed again, and in September of last year I had to make a thorough revision and to scrape out and dissect away some carious bone at the bottom of the former cavity. At present everything seems perfectly solid and cicatrized, and the patient uses his leg, as well as his high heel (for equalizing the shortening) allows him.

The case is very interesting in some respects. When a boy of ten, the patient doubtless had a severe acute osteomyelitis with spontaneous fracture of the thigh, but no necrosis of any great extent could have existed. Otherwise the suppuration would not have ceased for fully nine years. No doubt the pieces of dead bone, which were found at the operation a year ago, belong to a process of secondary necrosis. They also present a character quite different from that of the usual sequestrum. They look like dead cancellous tissue, and were found in a portion of bone which normally has no bony substance in its centre. The whole lower third of the thigh-bone proved to be filled with a new formation of bone that had undergone partial necrosis, apparently in a very chronic manner. The primary acute ostitic process did not immediately result in necrosis, though it must have been very severe, to judge from the spontaneous fracture of the bone, but it led to diffuse ossifying ostitis. Probably some of the infectious material remained encysted, until subsequently, in consequence of some noxious influence, it must have been all free, and by its injurious action upon the newly formed central osteophytic substance, caused necrosis of the same.

This secondary necrosis, or breaking down of newly formed substance, especially in the lower third of the femur, is not uncommon. About three years ago he presented before this Society three cases belonging to this group. In all of them extensive cavities in the lower part of the femur existed, and plastic operations, similar to that just described, proved to be effective. If let alone, these bone cavities in persons of somewhat advanced years will not heal. The cavity must be obliterated by a plastic inversion of the soft parts, which, in cases like these, where bony ankylosis of the knee-joint exists, are best taken from the anterior aspect of the thigh, the patella being removed. These operations must, of course, be done aseptically, if union of the flaps by first intention is to be expected, and it is by no means easy to do the operation with such thoroughness that a perfectly aseptic wound is left. The sharp spoon, chisel, and disinfecting fluids must be carefully used in all the remote corners and granulating recesses, which, if left untouched, will, of course, become the seat of suppuration.

He regards this method of dealing with bone cavities as a decided advance in modern surgery, and he cannot sufficiently recommend it, also, for certain cases of necrotomy in younger persons, where large cavities remain after the operation. There happens, though exceptionally, a certain kind of necrosis, so-called "necrosis disseminata," in which numerous sequestra are scattered all through the bone, lodged in small shallow lacunæ, which are generally connected with each other by narrow canals filled with granulations. [A number of illustrative specimens were here presented.] It requires, not infrequently, great care to trace these canals, and, after thorough removal of all the dead pieces of bone, eventually a thin involucrum may remain. He has, with very satisfactory results, tried to obliterate such cavities by inversion of the soft parts, and has done so on the thigh, on the tibia, and on the radius. On the thigh he has made use of the soft parts on the inner aspect; on the tibia he has formed flaps corresponding to the inner side of the bone. Into cavities at the head of the tibia he has, after the proposition of Neuber, to whom we owe this recent method, inserted tongue-like flaps, having their bases in the region of the tuberosity. Where very thick muscles must be cut across, as in the thigh, he takes care to tie all visible vessels when cutting down to the bone, nor does he trust to the effect of the compressing dressing before removing the constricting bandage. On the contrary, he removes the latter in these cases before applying the dressing.

Sometimes, while the limb is elevated, digital compression of the main artery is kept up, so that only a small quantity of blood is allowed to pass into the distal

portion at intervals. All vessels of any importance are ligated, and then, after inverting and fixing the flap, a compressing antiseptic dressing is applied. He usually changes the dressing on the second day, especially in summer. The second dressing may remain for one or more weeks, when, as a rule, union of the flaps will practically be obtained, and the open spaces left will show healthy granulating surfaces.

One more word about secondary necrosis in cases of osteomyelitis. There exists one variety of this affection which he might call secondary metastatic necrosis. For example, a boy had extensive necrosis of one tibia involving the ankle-joint. He underwent necrotomy; altogether eighteen sequestra, including two from the lower epiphyses, were removed. The healing process went on somewhat slowly, and the boy, though gaining in flesh, showed a pale, almost chlorotic appearance. He walked for several weeks on crutches, as he had done before the operation, when a subacute affection of his right humerus, at about its upper third, occurred, and after incision of an abscess, which contained very little pus, bare bone was felt. A sequestrum was removed, and the wound gradually healed. About one month later he developed the same trouble in the other os humeri at almost exactly the same point; and here, also, a central sequestrum was found. In another boy, who in the acute stage developed an osteomyelitis of the ilium, at the end of the first year (apparently from the constant use of canes) inflammation of the lower epiphyses of both radii and exfoliation of small sequestra took place. It will be recalled that he presented to the Society about two years ago a boy who had severe acute osteomyelitis in the hip-joint, with necrosis of the head of the femur, and spontaneous epiphyseolysis; about one year after the first attack, when suppuration was still present, after he had been using crutches for a good while, he developed a central bone-abscess in the lower part of the radius, just above the epiphysis, and in the course of that year the same condition existed in the upper third of the humerus, which had been exposed to the pressure of the crutch, and in the diaphysis of the tibia where he had bruised himself.

He emphasized the fact that in none of these cases, during the acute stage, had these regions secondarily affected participated in the diseased process, though in some of the cases multiple acute osteomyelitis was present. He cannot explain this occurrence, except by assuming that a mechanical lesion at certain points in a subject still affected with the poison of osteomyelitis (whether that poison is *staphylococcus aureus*, or another parasite), will favor its deposit at these points, so as to develop there its characteristic lesion. None of these secondary metastatic affections were of a very acute type, but were either subacute or chronic, perhaps in consequence of the diminished susceptibility of the already inoculated constitution.

A last practical word. We often see, in our hospitals, undue force used in applying the constricting elastic bandage for bloodless operations. This is superfluous, and only increases the paralysis of the circulation. He showed here Nicaise's bandage, which, except for the thigh in muscular subjects, will answer every purpose. It is a good plan to try on one's own limbs how little elastic pressure is necessary in order to arrest the circulation. In patients who are under an anæsthetic this force is still less, and he would advise never to apply the bandage before the patient is fully under the influence of ether.

DR. BRIDDON asked if the patient's leg was as much flexed when he first came under Dr. Lange's observation as it is at present.

DR. LANGE replied that it was; the flexion was due to the spontaneous fracture which occurred during childhood as mentioned in the paper. He added that for thirty-five years the patient had walked with his leg in that position.

DR. LANGE then read a paper on

A NEW OPERATION FOR PROLAPSUS ANI.

(See page 206.)

DR. SANDS inferred that the operation described was designed for cases in which a considerable amount of prolapse existed. Several operations had been devised for the cure of ordinary cases of prolapse, among others that of stroking the mucous membrane longitudinally with the cautery. He had known this method to succeed, but he had also seen it fail. It is not safe to produce a very deep eschar, because the peritoneal cavity might be opened. When the prolapse is of moderate extent it can usually be cured by the ordinary operation for hemorrhoids—*i. e.*, seizing the mass with forceps, drawing it down, and ligating it; the contraction which follows will cure the prolapse. This simple procedure, he added, has been very successful in his hands, and he prefers it to more serious operations. However, in aggravated cases, Dr. Lange's operation will doubtless be of benefit.

DR. LANGE remarked that the operation which he had described is not dangerous if antiseptic precautions are observed. The operator should be careful not to pass his sutures into the lumen of the gut. In operating for cancer of the rectum it is not necessary to introduce the finger into the bowel. He had encircled the tumor with an elastic ligature, and then removed the growth; by stitching the gut to the skin before the ligature is removed, loss of blood was avoided.

The patient had been under observation since the operation, four months.

Dr. Lange, in reply to a question from Dr. Briddon, said that he removed the coccyx in order that the action of the levatores ani might be less impeded. In answer to a question from the same gentleman, he added that both the anterior surfaces and the posterior borders of these muscles were brought together, because, otherwise, the ring would not be sufficiently narrowed.

DR. ABBE thought that as none of the rectal tissue was removed, but the lumen was simply narrowed, it seemed as if there was nothing to prevent the gut from eventually distending until it reached its former size.

DR. LANGE called attention to the fact that there were several buried sutures of silkworm gut which might cause suppuration, and subsequent cicatricial contraction of the parts.

DR. ABBE suggested that the tendency to redistention might be obviated by overlapping instead of simply approximating the divided muscles; it would not impair their contractile power. They would not be so likely to slide apart, as they would to pull apart when merely brought in contact. He thought that four months was

too short a time in which to judge of the success of a plastic operation.

DR. LANGE admitted that the future must decide as to the usefulness of the new operation. He promised to observe his cases carefully and to report the results.

NEPHRECTOMY FOR PYONEPHROSIS.

DR. LANGE exhibited a kidney which he had removed in November, at the German Hospital, from a woman about forty years of age; nephrotomy had been performed several weeks before, a large quantity of extremely offensive pus being removed. The kidney at the time of the first operation was as large as a child's head. Some improvement took place after the nephrotomy, but a diffuse discharge of pus continued, hectic symptoms appeared, and the patient's health failed so much that it was decided to remove the diseased organ. The usual lumbar incision was made, and the distal ends of the eleventh and twelfth ribs were resected in order to gain more room, because at this last operation the speaker had found that the kidney extended high up under the diaphragm.

The operation was not entirely a smooth one; the peritoneum at the upper angle of the wound was torn, in spite of the fact that the retractors were covered with flat sponges. The rent was covered with iodoform gauze during the operation, and was subsequently closed with catgut sutures, so that peritonitis did not follow. Furthermore, through the carelessness of an assistant, who exerted undue traction on the elastic ligature, by means of which preliminary compression of the pedicle was effected, it slipped and a very copious hemorrhage from the large renal vessels occurred. This was controlled by suitable forceps, such as are used in ovariotomy for seizing the sac or pedicle, and several strong silk ligatures were applied. Recovery took place without any disturbance, the wound being left open and packed with iodoform gauze. An intercurrent bronchitis caused some rise of temperature for several weeks.

The urine still contained a little pus and vesical epithelium and some albumin; it was light in color, and there was some suspicion that the remaining kidney was not quite healthy. Still, the patient's condition had been materially improved, and, above all, her pain was relieved.

Dr. Lange remarked that this was the second case in which, from urgent indications, he had removed one kidney while the other was not sound. The other patient was very comfortable, being placed under favorable hygienic conditions in a mild European climate; still, he had occasional attacks of pyelitis. From his experience in these two cases, the speaker was inclined to conclude that when urgent symptoms were present, the extirpation of one kidney was not absolutely contraindicated by a diseased condition of the other.

RENAL CALCULUS REMOVED FROM A PYONEPHROTIC KIDNEY.

DR. LANGE showed a calculus, weighing only fifteen grains less than an ounce, which he had removed from a lady, fifty-three years of age, who suffered from pyonephrosis. The presence of the stone had not been suspected, and only a small portion of it could be felt when the pelvis was opened, the rest being firmly encysted, so that it was necessary to dig it out with the aid of an elevator, sharp spoon, and forceps. As in a similar case in which the speaker had operated, the calculus had a number of irregular projections, which were so firmly imbedded in the calices, that it was by no means easy to dislodge it. As soon as the stone had been removed a fresh quantity of pus escaped, which had probably been shut in by the calculus. As the operation had been performed only five days before, it was impossible to say what would be the fate of the patient, although she was then in very good condition.

It was an interesting fact that in the previous history of the case there had been no symptoms pointing to renal calculus, and it was only three weeks before, after a fall, that she began to complain of pain in the affected side and general disturbance. The pyonephrotic tumor was then quite large and had probably existed for a long time previously as a hydronephrosis. A slight pain in the right lumbar region, which the patient had noticed during the past six years, must be attributed to disease of the corresponding kidney. The speaker had observed several cases in which renal calculi produced no pathognomonic symptoms; if the concretion was firmly imbedded in the calices, so as to remain stationary, neither hemorrhage nor great pain would be present.

VESICAL CALCULI AND HYPERTROPHIED MIDDLE LOBE OF THE PROSTATE REMOVED SIMULTANEOUSLY BY SUPRAPUBIC LITHOTOMY.

DR. LANGE also presented these specimens, which he had removed from a man upward of sixty years of age. The patient had suffered very severely for several years, and had been treated by the speaker himself about six years before, without obtaining much relief. Cystotomy had been proposed at that time, but this was declined. On opening the bladder, both calculi were found to be lodged in a deep diverticulum on the right side, near the entrance of the urethra. One of them was long and rounded, resembling one of the irregular processes of the renal calculus previously exhibited, so that it was possible that the stone might have descended from the kidney. Finding that the middle lobe of the prostate was considerably enlarged, he seized it with a vulsellum forceps, encircled it with a galvano-caustic snare, and removed it without much difficulty, the hemorrhage being slight. The wound in the bladder was kept open, in order to allow of effective local treatment. The patient's recovery was retarded by a very severe and protracted bronchitis. At the end of two months the wound was entirely healed, and he was then able to pass a full stream of urine, instead of being obliged to draw it with a catheter, as he had done for years. The urine was nearly normal. The patient's face had entirely lost that characteristic anxious, nervous expression so common in those suffering from painful chronic affections of the bladder.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, January 21st, 1887.

THE PRESIDENT, JAMES C. CAMERON, M.D., IN THE CHAIR.

REMARKABLE BROMIDE ERUPTION.

DR. BLACKADER exhibited a girl, æt. fourteen, who was affected with a remarkable eruption on the legs.

This consisted of a number of large oval patches five or six inches long and two or three wide on the extensor and inner surfaces of the calves of the legs. The eruption resembled somewhat a tubercular syphilide; it was raised and covered with a thick scab. On lifting the scab a moist surface was exposed, red, raised, and looking like exuberant granulations. The eruption had come out in smaller patches some months before these had coalesced. The girl had been taking bromide for the last two and a half years in doses of from half to one drachm daily.

Dr. Stewart said that it was well to combine the bromide with arsenic when they were given for any length of time.

Dr. James Bell exhibited a patient with the following history: A. B., æt. thirty, fell from a ladder with a chisel in his hand, and when striking the ground the chisel was driven deeply into his neck about one inch behind the angle of the lower jaw on the right side. Immediately there was a great gush of blood from the wound, which was arrested by a companion compressing the wound with a cloth. The hospital ambulance arrived, and on the way to the hospital the house surgeon, finding the bleeding again commencing, placed his finger in the wound. On arriving at the hospital Dr. Bell was sent for, and whilst examining the wound tremendous hemorrhage occurred; compression of the common carotid seemed to arrest the hemorrhage somewhat, so that vessel was ligated; but still the hemorrhage was as profuse as ever when the finger of the assistant was taken out of the wound. In order to find the bleeding point the wound was enlarged, but its depth was so great and the hemorrhage so tremendous, that a very inefficient search could be made. The blood seemed to be coming from a point near the base of the skull, which could be felt with the finger in the wound. It was now determined to plug the wound, which was done with three carbolized sponges well dusted with iodoform; these completely filled the wound. A firmly applied bandage was then put on over dry dressing. By this means the bleeding was completely arrested.

The man, who had lost considerable blood by this time, was very pale and had a small, flabby pulse; he was put into a warm bed with hot bottles, and stimulants were freely administered. Immediately after the accident the man was unable to speak and could not swallow. The first dressing was on the tenth day, when one of the sponges was removed; on the seventeenth day the second sponge was taken away, and the third sponge was not removed for a month. There was not the slightest suppuration throughout the case and the man recovered fairly well. He still had a hoarse voice and some difficulty of swallowing, and also contraction of the sterno-mastoid of the right side with a contracted pupil on the same side.

Dr. Bell said that he did not think the ligature of the carotid did any good, and that probably the case was one of wound of the internal jugular vein near the point, where it came from the jugular foramen. He thought that there had been some injury to the right pneumogastric nerve, if not complete division, with, at the same time, wound of the sympathetic trunk of that side, as evidenced by the contracted pupil, and slight drooping of the upper eyelid.

DUPUYTREN'S CONTRACTION.

Dr. R. J. B. Howard read a short paper on a case of Dupuytren's contraction of the little finger, in which he had operated according to the method of Mr. Adams, of London. The patient was a girl, aged twenty-two, who had always been healthy; no history of gout or rheumatism. The contraction was very marked. After dividing the bands subcutaneously at the two ends the lateral strands were then cut, and the finger was put in its natural position and held there with a splint and bandage. The wounds made by the tenotome healed well, but a slough formed in the dorsal surface of the little finger, and when this came away an ulcer remained, which was difficult to heal. He could not account for the presence of the slough, for the nerves supplying the skin of that part were not cut, and at no time was the pressure great. The result in consequence of the slough was not as perfect as it otherwise might have been, but a fairly straight and very useful finger was obtained. Dr. Howard also showed a beautiful dissection of a case of Dupuytren's contraction obtained from the anatomical rooms of McGill University.

PUERPERAL ECLAMPSIA.

Dr. A. L. Smith read a short paper on the above subject, and reported several cases. He strongly advocated the induction of premature labor at the seventh month in *all* cases of pregnancy where the amount of albumen was large and the urea deficient. In this way he thought eclampsia could be prevented, and fewer mothers and children would be sacrificed. Dr. Smith was of the opinion that the albuminuria of pregnancy was due entirely to pressure, and the proper treatment was to remove the cause.

Dr. Armstrong said he had seen many cases of albuminuria during pregnancy without convulsions occurring, and that when these came on it was time enough to induce premature labor.

Dr. Gurd stated that in some of the most severe cases of convulsions there was only a slight amount of albumen in the urine, whilst the patient might have a large amount of albumen and not have the slightest tendency to convulsions. He was altogether opposed to the induction of premature labor in cases of albuminuria. Dr. Gurd had found treatment of benefit. When there was albumen, with headache and œdema, he was in the habit of ordering the compound liquorice powder and cream of tartar, and also he put the patient on a milk diet.

Dr. Trenholme thought that the condition of the circulatory system is most important in these cases. If the heart is diseased, the case is of much greater gravity.

Dr. James Cameron disagreed entirely with Dr. Smith as to the necessity for inducing premature labor in albuminuria, and said that if this treatment were advised very serious results might follow.

CONGENITAL RETRO PERITONEAL CYST.

Dr. William Gardner showed some fluid removed from a retro-peritoneal cyst of the left loin. The patient, a female, æt. twenty-eight, unmarried, had an enlarge-

ment of the abdomen since childhood. In recent years the swelling had been growing larger, and she had been suspected of being pregnant. A week before she was seen by Dr. Gardner, she suddenly took ill with rigors, high fever, perspirations, vomiting, and severe pain and tenderness in the left loin. On examination a rounded, smooth tumor was found to occupy the left loin, enlarging the abdomen considerably on that side and extending beyond the median line to the left; it reached upward as high as the ribs and down to the brim of the pelvis. As the symptoms were urgent, it was decided to explore by abdominal section. A two inch incision was made in the median line below the umbilicus; on opening the cavity the cyst was found to be behind the peritoneum and intestines, the colon lay in front and in such a position as to render the management of the case too difficult; so the median incision was closed, and another made over the most prominent part of the tumor, about three inches to the left of the umbilicus. On reaching the tumor it was tapped, and seventy ounces of a dark, brown, turbid fluid, containing numerous crystals of cholesterine, removed. The opening was enlarged and its edges stitched to the edges of the abdominal wound, and a glass drainage tube left in. From the time of the operation the girl ceased to have pain, fever, or any other bad symptom; the discharge was slight and the cavity shrank rapidly, and when the patient was discharged, twenty-six days after the operation, the cavity was almost closed.

On examination the evacuated fluid was found to contain a quantity of pus. Dr. Gardner remarked that the cyst was evidently an old one, possibly congenital, growing near the kidney, and which had suddenly taken on inflammatory action. He also said that the cyst could have been evacuated through the loin posteriorly, but that he felt more at home in opening the abdominal cavity than the loin, and the result seemed to justify the course pursued.

CYSTO-SARCOMATOUS TUMOR OF OVARIES AND UTERUS.

DR. GARDNER exhibited a sarcomatous tumor of uterus and ovaries, removed from a married woman, æt. twenty-one, the mother of a child one and a half years old. The tumor was first noticed in October of last year and had grown rapidly, causing pain, emaciation, and interference with the functions of both bladder and bowels. The whole vaginal roof was a hard mass, and the os only made out with great difficulty. The whole floor of the pelvis was merged into one mass, and the operation was completed by encircling the cervix with Koeberle's clamp, and afterward amputating it and securing it with pins externally at the lower angle of the wound. The hemorrhage was free. The cavity was well washed out with warm water and drained. Everything went well until the sixth day, when the temperature rose and continued high with fluctuations for six days. She was now (19th day) quite convalescent. The wire was cut and the clamp removed on the third day.

(*From our Special Correspondent.*)

TERPINE IN CASES OF NEURALGIA.—DR. DUCROUX, in a paper recently read before the Société Médico-pratique, communicated notes of cases showing the good effects of terpine in cases of neuralgia.

The first case was that of a woman forty-seven years of age. Two years ago she was attacked with neuralgia consequent on occupying a damp house. A treatment of sulphate of quinine procured relief, but this was only temporary. Aconitine was subsequently administered, but the relief obtained was likewise temporary. On February 15, 1886, she was suffering from constant neuralgia on the right side of the lower jaw, in the right cheek and temple. There was also pain in the supraorbital notch, the mental foramen, and in the occiput. The patient complained of a constant sensation of heaviness in the head, and of cold in the right side of the head. 0.60 centigramme of terpine, in the form of three pills, was administered between meals during three days. On February 19th considerable relief was obtained. The pains and the sensation of cold disappeared, that of heaviness of the head, which had persisted for two years, also disappeared; the pains returned in a few days, terpine was again administered in the same manner as on February 25th. The pains disappeared, then returned, but in a milder form, without any heaviness of the head. Terpine was again administered on March 8th. Neuralgia again appeared; doses of 0.80 centigramme, in the form of four pills, were administered on March 10th, for three days. During the month of April these doses were repeated at intervals. At the end of April the occiput was sensitive, but all other pains had ceased. At the beginning of May and June terpine was again administered, the pains having reappeared. On June 15th the patient was able to go out without extra covering on the head. Dr. Ducroux is of opinion that the patient may be again obliged to have recourse to terpine, as the neuralgia reappears, though in a milder form each time. The therapeutic action of the terpine appears to fail after a few days. In cases of obstinate neuralgia it might be advisable to administer terpine every week during three years.

The second case was that of a married woman, thirty-five years old. At the age of twenty-two she had intermittent fever. From the age of thirteen or fourteen she had suffered from headache, from time to time. Menstruation ceased six years ago. A week ago she was attacked with pain in the right side of the head, differing from her habitual headache. This pain, which gradually increased, extended in front around the ear and over the temple and cheek, and behind over the mastoid region. There was pain in the external auditory channels. The pains were accompanied by a humming in the ears; 0.60 centigramme of terpine was administered in three pills, to be taken between meals. On April 29th the pains had disappeared, but the humming in the ears continued. 0.50 centigramme of sulphate of quinine was administered during three days. This remained without effect. A few days previous to May 17th the humming in the ears diminished, and took a different form. The sound in the ears was no longer that of humming, but of running water. The patient could neither hear herself nor others speak. 0.60 centigramme of terpine was administered during three days. The sounds in the ear diminished, and completely disappeared two or three days after the last pill was administered. Dr. Ducroux believes that the

disappearance of the pains was due to the use of terpine, and that the terpine exercised a certain influence upon the sounds in the ear.

The third case was that of a man, twenty-three years old. Fifteen years ago he was attacked with bronchitis, accompanied by hæmoptysis. In May, 1885, he was attacked with severe pain above the right eye, in the supraorbital notch and the occiput. The treatment administered was as follows: A blister applied to the temple and dressed with 1 centigramme of morphine; 0.60 centigramme of terpine in three pills, administered during three days. The first morphine dressing did not cause the pain to diminish; but the second, applied the following evening, caused a diminution of pain. The patient had then taken three terpine pills. As the improvement continued, only eight pills were administered in three days, after the second day. The neuralgia was completely cured. Dr. Ducroux attributes this cure to terpine, as the morphine dressing remained without effect.

Professor Ranvier.—This distinguished histologist and pathologist has been elected a member of the French Academy of Sciences.

A series of suits for damages was recently decided in the fourth session of the Superior Civil Court, Boston, before Judge Pitman. The cases are of great interest to physicians, as well as to landlords and tenants. The suits were brought to recover damages for sickness and costs of medical attendance, caused by alleged defective drainage. The plaintiff, Charles A. Cutter, leased a house of the defendant at No. 60 Allen Street, Boston, with the representation that the drainage was in good condition. Mr. Cutter set forth that, owing to the bad drainage, he and other members of his family had diphtheria, one child dying thereby. The defendant denied his liability, and, in defence, claimed that the drainage was good. The suits were in the names of five members of the Cutter family, and ended in substantial verdicts for the plaintiffs, the amounts being, respectively, $1600, $700, $300, and $250, each, in the last two cases.

Surgical Journal, February 10, 1887.

A prize of fifty thousand francs is offered by the French Minister of Education for a discovery rendering electricity economically applicable in the shape of heat, light, chemical action, mechanical power, transmission of messages, or treatment of disease. A committee, with M. Bertrand, of the Academy of Science, as its chairman, will adjudicate.

Professorship of Hygiene in Breslau.—A Professorship of Hygiene has recently been created at Breslau, to which Professor Flügge, of Göttingen, has been appointed, where he is Director of the Institute of Chemistry and Hygiene.

A New Medical Periodical.—A new medical periodical will appear on March 1st. It will be devoted to children's diseases and allied subjects, and will be called the *Centralblatt für Kinderheilkunde*. It will be published in Vienna, and edited by Dr. R. W. Raudnitz. The English editor is Dr. H. Ashby, of Manchester, to whom all papers for abstraction may be sent.

How Long should a Nervous Patient be Treated?—The question of how long treatment should be continued in a neurotic case when no evident benefit is produced, has recently been raised in a Hamburg law court. A medical man, having as a patient a merchant suffering from "nervousness," treated him by galvanism. Altogether he galvanized him 445 times, but the nervousness did not disappear. Then came the matter of fees. The sum claimed was £111 5*s*. The merchant disputed this on the ground that the treatment ought not to have been continued so long, as it was not producing any benefit. The court referred the matter to the medical board, which gave as its opinion that the doctor ought to have asked the patient, after some fifty sittings, whether he would like to continue them, as it was doubtful whether the treatment was doing any good. The court, however declined to accept this view, holding that it was for the patient to say when he had tried the treatment as long as he was disposed to pay for, and so gave judgment for the full amount claimed.

The Number of Medical Instructors and Students in Germany.—The Medical Faculty of Germany numbers 581 members, who are located as follows: In Berlin, 103; Leipzig and Munich, each 44; Breslau, 38; Bonn and Strasbourg, 30, and the remainder in smaller cities and towns. Vienna numbers a larger Faculty than Berlin, 122 instructors; it also excels the Prussian capital in its number of students, which, during the summer term of 1886, was 2289, that of Berlin being 1142. The proportionate number of students to each instructor is 11 in Berlin, and 18.5 in Vienna. The entire number of medical students in Germany during the summer term of 1885 was 8261, 14.2 students to each instructor. Berlin numbered 1142 of these; Munich, 1123; Würzburg, 796; Leipzig, 679; Freiberg, 544—*Deutsche Wochenschrift*, January 6, 1887.

MULTIPLE NEURITIS, AND ITS RELATION TO CERTAIN PERIPHERAL NEUROSES.

[Concluded from page 172.]

3. In a considerable number of cases of multiple neuritis no cause of the disease could be definitely ascertained. Great fatigue by walking, or by hard labor, and exposure to dampness and cold are assigned as causes in some of these cases, and may have acted as etiological factors. In others the disease seems to have developed spontaneously.

The following cases are cited as belonging to this class:

Observation XXI.—A perfectly healthy man, aged thirty-four, after a long and fatiguing walk was suddenly attacked with weakness of the legs, pain, and formication, which increased so rapidly that in two days he could not walk, and in eight days was totally paralyzed—legs, trunk, arms, face, and pneumogastric nerve being all involved. The paralysis was attended by severe pains, tenderness along the nerves, profuse perspiration, fever, and jaundice. Further, a diminution of sensibility, a loss of tendon reflexes, a loss of muscular sense, a rapid atrophy, with reaction of degeneration, were observed; and trophic disturbances, consisting of an abnormal growth of hair and pigmentation of the skin, as well as vasomotor disturbances in the form of œdema appeared. There were no fibrillary muscular contractions, no increase of muscular excitability, and no incontinence of urine or feces. During the following four months a gradual improvement took place, which went on to final recovery a year and a half after the onset. The only anomaly at that time was an absence of contractility of the muscles to the electric current, when excited through the nerve.[1]

Observation XXII.—A female, aged forty-two, previously in good health, was attacked, on October 1st, with pain in the back and in all four extremities, attended by great weakness, which increased so rapidly that on October 13th there was found to be an almost total paralysis of both legs, of the trunk, and of certain muscles of the arms. The pains were accompanied by a feeling of formication and a painful sensation of tingling. When first seen by Dr. Guttmann there was total paraplegia, slight movements in fingers and toes being the only motion possible; the muscles were all relaxed and flabby, were much atrophied, were tender to pressure, and a few of the smaller muscles showed slight diminution of faradic excitability. There was no disturbance of sensation. The tendon reflexes were abolished. The sphincters were not involved. The temperature was normal, but the pulse was unduly rapid. There were no bulbar symptoms. Under large doses of iodide of potassium, and the application of faradism, the patient recovered completely in the course of three months.[1]

In some of the cases of this form the early pains were located in the joints, and led to the diagnosis of rheumatism. The fact is merely mentioned to call attention to the possibility of mistake. A careful examination will never fail to correct it.

Symptoms.—Turning now to the consideration of the individual symptoms of multiple neuritis and their course, we are at once impressed by their number and variety.

The *sensory symptoms* are the earliest to appear and the last to pass away. In the majority of the cases on record, from whatever cause, numbness, tingling, or formication ushers in the disease. These forms of paræsthesiæ begin in the feet and hands, and extend to the knees and elbows. They may be associated with burning, stretching, boring, or tearing sensations, which distress the patient especially during the onset. But all such sensations usually subside as the affection reaches its height. Their recurrence, as the case goes on, may be regarded as a favorable symptom, however annoying, for they frequently precede recovery, and are among the last evidences of the disease to disappear. Pain is usually present as well as paræsthesiæ. It may occasionally be sharp in character; but is usually moderate and not continuous. At times it may be lancinating, and so severe as to necessitate the use of morphia. But it is rarely as distressing as in cases of locomotor ataxia. Tenderness in the nerves and muscles is a constant symptom. It may be so marked that the limbs cannot be moved or handled, and thus it may interfere with the application of electricity and massage. When the tenderness and pain are referred to the joints, as not infrequently occurs in the early stage of the disease, the case may be mistaken for one of acute articular rheumatism, and if the joints are swollen or the limbs œdematous the difficulty of diagnosis is greatly increased.

In addition to these subjective feelings some demonstrable disturbance of the various sensations is usually present. Hyperæsthesia to touch, and also to electricity, is not infrequently observed during the first few weeks. It is usually followed by some anæsthesia, although this rarely becomes complete. In some cases the loss of

[1] R. H. Pierson: Ueber Polyneuritis Acuta. Volkmann's Klin. Sam., 1883, No. 229.

[1] Guttmann: Deut. med. Wochenschr., 1884, No. 19.

tactile sense is quite evident from the onset, either limited to the cutaneous distribution of some special nerve, in which case oddly shaped areas of insensibility will be found, or, as is most often the case, about uniformly distributed over the distal parts of the extremities. When the anæsthesia is at its height the patient has difficulty in locating a touch upon the limb, even though he feels it. The transmission of pain and temperature sensations is always delayed, but the impressions are usually felt quite acutely. The sense of pressure has been tested in only a few cases, and in those it was decidedly impaired. The muscular sense escapes any affection in some cases, but in others is the most profoundly disturbed of all the senses. When it is involved the incoördination and ataxia are well-marked symptoms, and, as already stated, some of the cases have been mistaken for locomotor ataxia, because of the predominance of the disturbance of muscular sense.

These sensory symptoms are usually limited to the forearms and hands, and to the legs and feet. In a few cases they have involved the entire extremities, and even the trunk; and one case of facial tingling with anæsthesia has been recorded.[1] The skin reflexes are usually preserved.

The special senses are rarely affected in multiple neuritis. It is true that optic neuritis has occurred in a few cases, and in two cases hearing as well as sight has been affected. These cases prove that no nerve can be said to be exempt from implication in this disease, but the liability to affection seems to be slight in the case of the nerves of special sense.

The *motor symptoms* are as marked and as important as the sensory. Paralysis, beginning as simple weakness, with a feeling of fatigue on any exertion, gradually increases in severity until at the height of the disease it becomes complete. It usually comes on rapidly, so that within two weeks the patient is helpless; but it may be less sudden, and not deprive him of the power of walking and of using his hands for two or three months. In a few cases a very acute onset is recorded, all the symptoms developing within three or four days. The distribution of the paralysis is not uniform at the outset. It may develop in the muscles supplied by a single nerve, and advance to others; it may begin in all the muscles of the legs, and then involve those of the forearms; it may commence in all four extremities at once. It is always more severe in the muscles which move the joints of the feet and hands, and the ankles and wrists. It rarely invades those which move the knees and elbows. When the disease is fully developed all the muscles below the knees and elbows are much weakened or totally paralyzed. In a few cases those of the thighs and arms are involved also, and occasionally the muscles of the trunk and those of respiration become affected, and the patient dies. When such a paralysis makes rapid progress and involves all the body, the case resembles Landry's paralysis. But in multiple neuritis, as has been already stated, the disease does not creep up from legs to thighs, and then to trunk and arms, as in Landry's paralysis. It spreads from feet to hands, from legs to forearms, and the trunk is invaded only at the end, and in Landry's paralysis sensory symptoms are wanting. In some cases of multiple neuritis the cranial nerves become involved; those of the eye and of the face being most liable to invasion. It is only in fatal cases that the action of deglutition has been affected; and when the pneumogastric is invaded, and the heart becomes rapid and irregular, the prognosis is always grave.

The paralyzed muscles are relaxed, flabby, and atrophied; they may or may not lose their mechanical irritability, but their normal tone is always lost, and hence the so-called tendon reflexes are abolished.[1] To the electric current their excitability is very rapidly and markedly changed; but the conditions which have been observed are quite various. Sometimes there is a simple diminution of excitability, and then a very strong faradic or galvanic current is needed to produce contractions. Frequently all faradic excitability is lost, and then the muscles react to a galvanic current only. In this condition it may require a very strong galvanic current to produce contraction, and this fact is quite pathognomonic of neuritis. For in anterior poliomyelitis, where the muscles respond to galvanism only, it does not require a strong current to cause a motion until some months after the invasion. The action of the different poles is not uniform. In many cases the contraction of the muscle, when stimulated with the positive pole, is greater than when stimulated with the negative pole, and the contractions may be sluggish. Then the reaction of degeneration is present. But in some cases the normal condition is found, and the negative pole produces stronger contractions than the positive pole. If the muscles that are not paralyzed be tested, the same electrical changes may often be discovered in them. A loss of faradic irritability and a marked decrease in the galvanic irritability of the muscle and nerve are, therefore, important symptoms of multiple neuritis. And as the disease goes on to recovery, a gradual increase in the galvanic irritability occurs, a fact which is often of much aid in prognosis if careful measurements of the strength of current used be made by the galvanometer. I am accustomed to record such measurements upon charts, and thus to obtain an electric curve for each muscle which is paralyzed.[2] These curves enable one to judge of the progress of the case quite accurately, and when the line is advancing steadily toward the normal point, after a great deflection or after a stationary level, the prognosis is very favorable.

As a result and accompaniment of the paralysis *abnormal positions* are assumed by the limbs. The dropped wrist and dropped foot are quite characteristic of multiple neuritis. But other deformities may be present. In a few cases there have been extreme contractures of all the extremities in flexed position. And not infrequently the appearance of the claw-shaped hand, and some one of the various forms of talipes indicates a serious shortening of one set of muscles, and corresponding weakness of its opponents. These deformities usually subside as the power returns, or if they do not they can be corrected by proper manipulation and by

[1] A few [illegible] tested [illegible] by Strümpell and Möbius': Münchener Wochenschrift, 1886, No. 34, and in Brit. Med. Journ., Jan. 1, 1887.

[2] Electric Charts: Journal of Nervous and Mental Diseases, February, 1887.

apparatus. In a few cases it has been necessary to resort to tenotomy, but a permanent deformity has not been recorded.

The *vasomotor and trophic symptoms* are less constant than those already described. In some cases marked œdema has been an early and a permanent symptom. This may develop in the feet and hands, or may appear about the joints. It usually is temporary. The circulation is not impaired any more than is customary in a limb whose muscles are inactive, and coldness and cyanosis are rarely sufficient to attract attention. Sometimes profuse perspiration is a noticeable symptom, being limited to the paralyzed parts. It may be offensive, and by its evaporation always causes a complaint of coldness. In other cases glossy skin makes its appearance early and remains until regeneration of the nerves begins. Its disappearance in one of my own cases was the first sign of recovery in the lower extremities. Other forms of trophic disturbance are rarely met with in multiple neuritis. And this is quite remarkable in view of the fact that it has been the tendency of late to refer such trophic affections as ulcerations, bedsores, gangrene, pemphigus, and various eruptions to lesions of the nerves.[1] It is true that inflammations of the joints, resembling those appearing in acute rheumatism, sometimes occur at the onset of neuritis; but as they disappear quickly while other symptoms remain, it is improbable that they are to be traced to the changes in the nerves. They may be due to the infectious agent, or to the same obscure cause which sets up the neuritis, or they may be evidence of an attack of acute articular rheumatism, which is in turn followed by neuritis; but they cannot be described as trophic symptoms of the disease: otherwise they would be more constant in their occurrence and more permanent in their duration.

A negative symptom of some importance is the absence of any interference with the automatic acts controlled by the sphincters.

One word about the onset. Occasionally it is sudden and accompanied by a marked febrile movement, with chill, and temperature of 103° to 104.5° F. The fever may persist for several days, but usually subsides spontaneously, and does not recur. In a few cases there has been a constant elevation of temperature from one-half a degree to one and a half degrees above the normal; and an increase in the rapidity of the pulse throughout the disease has been noticed. A pulse of ninety need give no alarm, but if it runs up to one hundred and forty, and becomes irregular, there is reason to believe that the disease has attacked the vagus nerve, and then the prognosis becomes serious, though not by any means hopeless.

The duration of the disease varies considerably in different cases. An average of twenty-five cases gives seven months as the probable time required for complete recovery. But in these cases the duration varied from two months, in the most favorable, to sixteen months in the most refractory.

The disease is more common in males than in females, excepting the form produced by alcoholism. Of forty-seven non-alcoholic cases thirty-three were males.

All ages are liable to be affected, but in the records of multiple neuritis, excepting the form produced by diphtheritic poison, the cases recorded do not include any children.

That children may be affected, is, however, not at all improbable. Dr. H. D. Chapin, of this city, has described four[1] cases of atrophic paralysis in children in which the presence of sensory symptoms, pain and muscular tenderness, and the steady progress toward recovery pointed to the existence of multiple neuritis. The cases were such as are usually called infantile paralysis, but there were points of difference (viz., the existence of sensory symptoms) which removed them from this category. Leyden called attention to the possibility of mistaking neuritis for poliomyelitis in his first article upon the disease, but he referred to adult cases rather than to children's cases. And if the surmise of Chapin should be substantiated by autopsy, it might be necessary to conclude that in children as well as in adults the majority of cases of supposed poliomyelitis which recover, are cases of multiple neuritis.

In adults, out of 50 cases, 6 were between the ages of 18 and 20; 8 between 20 and 30; 20 between 30 and 40; 8 between 40 and 50; 5 between 50 and 60, and 3 over 60 years of age.

Diagnosis.—While the individual symptoms occurring in the course of multiple neuritis are not different in character from those found in spinal cord diseases, the diagnosis can usually be reached with very little difficulty when their combination, the causation, and the course of the case under examination are considered. The varying combination of the symptoms possible has been manifest during their description and it is not my intention to review them again. There are, however, three combinations which resemble very closely, respectively, anterior poliomyelitis, locomotor ataxia, and diffuse myelitis, and to these attention must be directed.

Atrophic paralysis, with reaction of degeneration and loss of reflex, is common to anterior poliomyelitis, and some cases of multiple neuritis. In the latter, a more gradual onset, preceded and attended by numbness and pain, tenderness in the course of the nerves, tenderness in the muscles, and the persistence of sensory symptoms after the invasion, will remove all doubt regarding the diagnosis. When these symptoms are not clearly marked, the distribution of the paralysis in symmetrically situated muscles, especially if these muscles are supplied by single nerves, and the further extension to muscles in other nerve domains, rather than the affection simultaneously of muscles which are grouped physiologically (*i. e.*, act together to perform one function), will point to neuritis. In neuritis the paralysis advances more or less gradually, while in acute poliomyelitis there is, after the onset, a subsidence of the paralysis in some of the muscles first involved. And lastly, as the case goes on, a gradual complete recovery will be far more frequent if it was originally a case of multiple neuritis.

Ataxia, loss of knee-jerk, pain, and sensory disturbances, including a loss of muscular sense, Romberg's symptom, and optic neuritis are common to locomotor ataxia and multiple neuritis. In the latter the relatively

[1] Reynaud's disease has recently been ascribed to peripheral neuritis. See J. Wiglesworth, Brit. Med. Journ, Jan. 8, 1887.

[1] Painful Paralysis [illegible] New York Med. Journal, January 15, 1887.

rapid onset of the ataxia, which follows closely upon the sensory symptoms; the prominence of numbness and anæsthesia, rather than of lightning pains; the extreme degree of the anæsthesia and analgesia; the tenderness of muscles and nerves; the usual occurrence of some degree of actual paresis with atrophy and R D; and the absence of bladder and sexual symptoms will point inevitably to the diagnosis. Furthermore, the ataxic form of neuritis only occurs after poisoning with alcohol or arsenic, or as a sequel of diphtheria, and the establishment of the causation will aid the diagnosis. Here, again, the course of the case toward recovery, with the return of the knee-jerk, will decide in favor of neuritis, if the diagnosis has not been reached in an early stage.

There are very few symptoms of diffuse myelitis which are not found in cases of neuritis. But cases of diffuse myelitis of the type of Duchenne, paralysie générale spinale subaigue ascendante, are very rare, and, indeed, by Leyden it has been affirmed that all such cases are multiple neuritis. Other authorities dispute this assertion, and leave us to establish points of difference. These are as follows: In neuritis, affections of the functions of micturition and defecation do not occur. Girdle sensation is very rarely mentioned as a symptom. Bedsores and cystitis have not been observed. The advance of the paralysis is not from the legs to the thighs and trunk, and then to the arms; it is usually from the legs to the forearms, the thighs and trunk escaping, and, as a rule, the distal portions only of the extremities are paralyzed. If the muscles of the abdomen and respiration are involved, it is only in rapidly fatal cases. In neuritis there is usually some ataxia, and loss of muscular sense is quite evident, while in some at least of the cases of myelitis of Duchenne there were no sensory symptoms at all. Finally the tenderness of muscles and nerves, and the absence of tenderness to pressure or to heat in the spine would decide in favor of neuritis. The diagnosis from meningitis of the cord, from tumors or hemorrhages into the cord, or from general paralysis of the insane, would rarely present any difficulty to one who was familiar with the symptoms in those affections, and who knew the prominent features of multiple neuritis.

No small difficulty may be encountered, however, in settling the question whether in a given case we have to deal with multiple neuritis alone, or with multiple neuritis which is complicated by myelitis. The importance of the question is evident since the prognosis in the two conditions is very different. And the number of autopsies on record in which this complication has been demonstrated, though few, is sufficient to make a decision of the question necessary.[1] The following points may enable a determination of the question to be reached: (1) As long as a case is increasing in severity, or in the extent of the symptoms, no one can determine the extent of the lesion. It is only when its course has become stationary that the question of exact limitation will arise. Many cases remain practically without improvement for three or four months, and then gradually recover. A stationary condition alone does not, therefore, excite fear of a complication. But neuritis tends spontaneously to recover, the process of regeneration beginning soon after the degeneration has ceased. If, therefore, there appears to be no improvement of the condition after the fourth month, the probability is either that the cause of the disease has not been removed, or that a myelitis has developed and prevents recovery. (2) The course of a case of neuritis is quite characteristic, the symptoms reaching their maximum in a short time, and then subsiding. If, after a stationary period, further symptoms develop, we must believe either that the cause of the disease is renewed—*e. g.*, the use of alcohol—or that myelitis has begun. The symptoms of such a myelitis will be an increasing weakness, and more rapid and progressive atrophy of the muscles; a gradually decreasing degree of galvanic excitability in the paralyzed muscles; a loss of pain and temperature senses, which, as a rule, are not affected in neuritis; a decrease in the paræsthesiæ, and an increase in the degree of anæsthesia; the development of loss of control over the sphincters; the occurrence of bedsores, furuncles, eruptions of a bullous nature; and the beginning of cystitis. (3) On the other hand, if the symptoms are gradually improving: if the power gradually returns; if the anæsthesia decreases, and is succeeded by paræsthesiæ, however disagreeable to the patient; if the galvanic excitability becomes gradually more acute in the muscles, so that the electric curve approaches the normal line; if the faradic contractility returns in the muscles; if the tenderness of muscles and nerves decreases; and if the glossy appearance of the skin disappears, it may be stated that no complication of myelitis has occurred, and that recovery, though possibly prolonged, will at length result.

Another question of diagnosis must also be considered. It is found that in no small number of cases of locomotor ataxia multiple neuritis develops as a complication. How can we determine when this complication exists? The symptoms of the two diseases may be so nearly identical that difficulty arises in distinguishing them. When they coincide it is equally difficult to determine to which any given symptom belongs. Pitres and Vaillard,[1] who have considered this subject most carefully, affirm that there is no constant relation between the severity of the central and peripheral lesions when they coincide. But there are certain symptoms which develop in some cases of tabes, but not constantly, which may be looked upon as accidental, and thus traced to neuritis. Such are the appearance of plaques of anæsthesia and analgesia of limited area, muscular weakness or paralysis of limited extent, trophic disturbances in the skin (*e. g.*, perforating ulcer), nails, joints (*e. g.*, Charcot's disease), bones (*e. g.*, spontaneous fractures), and teeth (*e. g.*, spontaneous falling out), and possibly the various crises referable to the viscera and larynx. In cases which competent observers have examined, peripheral neuritis has been found *post-mortem* in the nerves supplying the parts in which these symptoms appeared. It is, therefore, reasonable to conclude that in any case of locomotor ataxia in which the symptoms develop, we have to deal with a posterior sclerosis which is complicated by a peripheral neuritis. And here again the distinction has a bearing upon the prognosis, for the symptoms of the accidental kind may pass off, while those due to the central lesion

[1] Oppenheimer, *Am. Journ. Med.*, xi. 232. Leyden: Charité Annalen, 1878. Fenwick: *Guy's Hosp. Rep.*, 1884.

[1] Pitres et Vaillard: Des névrites périphériques chez les tabétiques. *Journ. de Méd.*, 1887, p. 577.

will remain. While these conclusions of the French authors are of importance, it must be noticed that their claim that trophic disturbances are due to a complicating neuritis is by no means substantiated by the history of cases of multiple neuritis, in which, as we have seen, trophic disturbances of the varieties mentioned do not often occur.

Prognosis.—The prognosis in multiple neuritis is good, provided the exciting cause can be removed. The only cases which form an exception to the rule are those whose constitutions are much impaired by excesses or by other diseases; those who have so far indulged in alcohol or are so completely soaked with arsenic or lead as to be unable to throw off the poison; and those in whom the disease begins with great suddenness, advances rapidly, and involves the phrenic and pneumogastric nerves. These cases die either of respiratory paralysis or of some complication. When a case has reached the stationary period the prognosis is generally favorable, and if the encouraging signs of recovery already mentioned begin to appear a cure may be promised. The possibility of the complication of myelitis must not, however, be overlooked, and if it occurs the prognosis becomes at once unfavorable. Even in serious cases of alcoholism, with gastro-intestinal and cerebral symptoms, if the acute stage is safely passed and all alcohol be removed from the patient's diet, recovery from very extensive paralysis will occur. The cases of diphtheritic paralysis and ataxia usually recover without treatment. The cases occurring with syphilis and tuberculosis are not so uniformly favorable, although the former usually respond promptly to specific treatment, and even the latter may recover wholly. In epidemics, the percentage of mortality has been found to vary, but is usually low.

Treatment.—The treatment of multiple neuritis requires patience, but receives the reward of success. As we have already seen, the majority of the patients recover, and it is probable that, if the cause of the affection were removed and the patients placed in favorable circumstances, expectant treatment would alone be sufficient. It is, however, not advisable to let therapeutics play a passive part. The course of the disease can be altered and its duration much shortened by active interference. In the stage of invasion the free use of salicin, salicylic acid, or the salicylate of soda seems to have important results. These remedies cannot be said to act as promptly as in cases of acute articular rheumatism, but the consensus of opinion is that their effect in multiple neuritis is very marked. They should be given, as in acute rheumatic fever, in large doses until noticeable effects are obtained. They should be combined with the bromide of potash or soda, partly because these drugs counteract unfavorable symptoms produced by the salicin compounds, and partly because in the hyperæsthetic irritable condition attendant upon the invasion of the disease they are indicated. This condition may require stronger sedatives, and not infrequently morphine must be employed to give relief from the excruciating pains. The pains are often relieved by hot or cold applications to the limbs; but as the muscles are often exceedingly tender, ordinary applications cannot be made. It is then advisable to use evaporating lotions, preferably those containing chloroform, which may be soaked into light cambric or gauze, and gently placed upon the limbs, which lie upon the softest pillows, or which may be more comfortable if the patient is put upon a water-bed. Applications of a five per cent. solution of carbolic acid have also been of use. If cool applications prove intolerable, heat may be employed. The limbs may be enveloped with cotton and covered with oil-silk, a light bandage keeping these in place; or they may be frequently bathed in hot water, and hot bottles placed against them, some soft substance intervening. One of my patients found great relief from the paræsthesia by cold douches, while another preferred the use of hot water. It is best to let the patient decide as long as the application has to be made for the relief of pain. Gentle friction with oil of cocoanut often affords comfort. In the chronic stage, as we shall see presently, heat is to be preferred to cold. Cases which are distinctly syphilitic, if such occur, should be treated from the outset with inunctions of mercury and large doses of iodide of potash. I believe that both these drugs should be employed together, even in the tertiary stage of syphilis, and it is my experience that all syphilitic nervous lesions, whether central or peripheral, yield more promptly to their combined use than to the employment of either alone. Malarial cases must be treated with quinine or Warburg's tincture. In non-malarial cases quinine has proved of no avail. In cases which are due to poisoning of any kind the first necessity is to eliminate the toxic agent from the system, and the second to prevent any further ingestion of the poison. Iodide of potash aids in the elimination. The second indication is easily fulfilled when arsenic or lead are the toxic agents, but when the case is due to chronic alcoholism special precautions are needed. Alcoholic cases require from the outset special treatment. The condition at the time of the onset of the paralysis may be one verging upon delirium tremens. If all alcohol is suddenly removed, without due care to supply some other heart-stimulant and to secure the perfect nutrition of the patient, serious collapse may ensue. The first necessity is, therefore, to take care of the general condition of the patient. If this will admit of the immediate withdrawal of all alcoholic stimulation, it should be done; if not, the alcoholic beverage must be immediately reduced in quantity, and as soon as possible wholly cut off. The use of milk diet, or kumyss, or pancreatized milk, or, if necessary, rectal alimentation, will be followed by a gradual recovery of the power of assimilation, and as soon as the patient ceases to lose weight all alcohol may in any case be safely stopped; its elimination by the intestines and kidneys may be hastened by appropriate means, and cerebral symptoms, if they arise, may be treated as in other cases of alcoholic intoxication. But it is in the chronic stage, when the patient is gradually recovering, that the vigilance of the physician is called into play to prevent a renewal of the poisoning. It is amazing that patients who know perfectly the injurious effect of alcohol upon them should insist upon getting it. But it is done. And when these patients are surrounded, as is often the case, by sympathizing friends, or servile domestics, or unscrupulous nurses, who do not appreciate the importance of total abstinence either for themselves or for the patient, they often succeed in baffling all attempts to deprive them of the favorite drink. It is only when they are watched constantly by persons who can be

implicitly trusted, and who have sufficient authority to cut off all surreptitious supplies, that the physician can feel sure that his commands are obeyed. And this precaution is by no means needless, even when it is probable that family servants are trustworthy. For the continued pleading and remonstrance of the patients may corrupt the best of attendants, especially if accompanied by threats of discharge at a future day. It is, therefore, necessary to place these patients under the surveillance of trained nurses from the start, or to remove them to an institution where they are under control.

In the chronic stage the drugs which are of greatest service are strychnia and arsenic. Strychnia may be given in doses of $\frac{1}{60}$ to $\frac{1}{30}$ gr. t. i. d. and it is well to combine it with phosphoric acid and the syrup of the hypophosphites. Arsenic may be used in tablets or pills containing $\frac{1}{50}$ to $\frac{1}{30}$ gr. t. i. d. or in Fowler's solution five to eight drops t. i. d. The use of iron with these two drugs will be indicated in the majority of cases where there is attendant anæmia. In alcoholic cases both arsenic and strychnia may increase the mental irritability, but should be continued unless this becomes too great. I have seen benefit from both of these drugs, and think it well to employ them alternately, using each for about two weeks at a time.

The remedies used in the chronic stage have two objects: one is to increase the rate of repair in the nerves; the other is to keep the nutrition of the muscles as good as possible. While the drugs mentioned probably meet the first indication, there are other remedies which meet both. These are massage, warm baths, and electricity. The proper manipulation of the limb increases the circulation in it. The increase of circulation brings fresh supplies of material to the nerve which is undergoing repair; it also aids the nutrition of the muscle, which would otherwise be decidedly affected by the sluggish flow of venous blood, due to the lack of functional activity. As soon, therefore, as the active progress of the disease is checked, and the muscular tenderness has sufficiently subsided to allow the limbs to be rubbed, this potent remedy should be employed daily.

Allusion has already been made to baths and douches in the early stage, for the purpose of quieting sensory symptoms. In the chronic stage the object is a different one. Like massage, warm baths and douches stimulate the circulation and aid the nutrition and reparative processes in progress. Hence they are to be used daily. And if the warm bath be given at night it will secure not only a local action but produce a general sedative effect, insuring quiet rest. In multiple neuritis, as well as in many other nervous affections not due to anæmia, a warm bath at night or a warm douche to the neck and spine is far preferable to, and more efficacious than, the majority of hypnotic drugs in causing a good night's sleep.

The last agent to be mentioned is electricity. It is, however, among the first in importance, and in its use it is necessary to know what object is sought in its application. There is first the object of increasing the progress of nerve regeneration. This may be attained by the application of a constant galvanic current to the degenerated nerve, passing the current through the nerve in either direction, or in both alternately. A mild current should be employed, its strength being measured by a galvanometer. The strength of the current will depend: (*a*) on the size of the sponges placed upon the skin, (*b*) on the pressure upon the sponges, (*c*) on the resistance of the skin, and (*d*) on the number of cells of the battery used.

If the sponges are two inches in diameter, six milliampères are enough; if they are three by five inches in measurement, twenty milliampères should not be exceeded. If no galvanometer is used the strength of the current employed is uncertain. But it is to be remembered that the current grows stronger the longer it passes, since the skin resistance is gradually overcome; and, therefore, if the strength is measured in cells, the number of cells used should be decreased gradually during the application. As so few practitioners use a galvanometer it may be well to state that with large sponges (*i. e.*, three by five inches) wet with warm water a freshly filled bichromate of potash battery will give nearly one milliampère of strength for every cell used during the first three minutes, provided the sponges be put on any part of the body except the soles of the feet or the palms of the hands, and pressed firmly upon the skin. After the first three minutes the body resistance decreases, so that when twenty cells are used to start with, one should be cut off every half minute until the number is reduced one-third. The duration of the application should be about ten minutes to each limb. During this time the distal sponge should be passed over various parts, so as to include all the nerve-branches in the current; the central sponge should be put over the nerve-trunk high up on the limb. The current should be begun and stopped gradually, and never suddenly broken; applications may be made daily.

The second object to be obtained is to reëstablish the conduction of impulses in the regenerated nerve. This is secured by the method just described. It may be attained by the use of faradism, the interrupted secondary current being sent along the nerves by placing one pole over the nerve-trunk and passing the other over the skin of the limb. The strength used should be just sufficient to be felt distinctly through the palms of the operator's hands. The third object sought is to maintain the nutrition and function of the muscles by exercising them, and thus preserving their normal irritability. This cannot be done by a faradic current as long as they do not contract to it. The galvanic current must therefore be employed. But now it is not a steady current which is needed, for this does not cause any motion. It is only when the steady current is suddenly broken and renewed that the contraction occurs. Hence place one pole over the trunk of the nerve and the other upon the muscle, and with an interrupting electrode make and break the current at the pole which is on the muscle. The pole which produces a contraction with the least current possible is the one to be applied to the muscle. This is in RD, the positive; in normal conditions the negative pole. Each muscle should be exercised for three or four minutes every other day. When electrical treatment is thus employed very marked improvement is observed, which can be measured accurately if a galvanometer is used, since every week will show a change of the strength of current needed to produce muscular contractions toward the normal.

The treatment must be kept up, in the chronic stage, until recovery is complete.

If contractures have occurred in the paralyzed limbs persistent massage may overcome them. If it does not, they are to be treated on general surgical principles.

ORIGINAL ARTICLES.

BACTERIOLOGICAL NOTES.

By George M. Sternberg, M.D.,
Major and Surgeon, U. S. A.

The "gonococcus" of Neisser. In The Medical News of January 20, 1883, the writer gave a detailed account of a series of experiments made for the purpose of determining whether the infective virulence of gonorrhœal pus is due to the micrococcus—so-called "gonococcus" of Neisser — constantly found in the pus-cells, in cases of specific urethritis.

In this paper the results obtained were summarized as follows:

(*a*) Microscopical examination of numerous specimens of gonorrhœal pus, from a number of cases, has demonstrated the constant presence of the micrococcus first observed in Baltimore in the summer of 1881.

(*b*) Upon inoculating a sterilized culture-fluid (beef-tea, or rabbit *bouillon*) with a small quantity of gonorrhœal pus at the moment of its escape from the meatus urinarius, and placing this in a culture-oven for a few hours, an abundant development of micrococci takes place.

(*c*) These micrococci present in all cases the same morphological characters, and no other microörganisms than these make their appearance in a hermetically sealed culture-flask, inoculated as above indicated.

(*d*) These micrococci, introduced beneath the skin of a rabbit, produce no noticeable result.

(*e*) Culture-fluids containing these micrococci introduced into the healthy male urethra do not give rise to specific urethritis, or to any other noticeable result.

(*f*) A culture-fluid containing this micrococcus, upon being added to acid urine recently passed and free from microörganisms, causes it to undergo the alkaline fermentation.

(*g*) Urine which has spontaneously—that is, without resort to experimental inoculation—undergone alkaline fermentation, contains a micrococcus indentical in appearance with that obtained by cultivation from gonorrhœal pus.

In a second paper published in The Medical News of October 18, 1884, the results of a second series of culture and inoculation experiments are given. Again I obtained, by cultivation, from gonorrhœal pus the micrococcus I had previously experimented with from the same source, and again I failed to obtain any positive results from the introduction of these cultures into the urethræ of healthy individuals. In the paper referred to I say:

"The uniform presence of this micrococcus in specific purulent discharges from the urethra or conjunctival sac is now well established, while the recorded observations indicate that it is not found in non-specific discharges from mucous surfaces. The presumption is, therefore, very strongly in favor of the view that the microorganism in question is connected with the infective virulence of these discharges."

This presumption was not sustained by my own inoculation experiments, and I did not consider the successful inoculation reported by Bockhardt convincing for the following reason. Bockhardt produced a typical gonorrhœa in a paralytic patient by introducing into his urethra a *fourth* culture made upon flesh-peptone-gelatine. Now it seemed to me

quite possible that some pus-cells from the original material might have been carried over with this fourth culture made upon the surface of a solid culture medium. A similar criticism is made by Flügge in the second edition of his admirable work, *Die Mikroorganismen.* He says:

"This case is not quite free from objection, because later researches have shown that no growth of the cocci takes place upon flesh-peptone-gelatine. Perhaps, therefore, the positive result, which cannot be doubted, is due to the carrying over of cocci which, however, have not grown in the culture. This does not seem impossible, as the transference of pus to culture and from one culture to another was made with great masses—'*grossen Mengen*'—and the fourth generation was used."

Aside from the possibility of error through the transportation of some of the original material, which I have suggested in my paper referred to, and in my book,[1] we have in the quotation from Flügge the definite statement that the micrococcus in question does not grow upon flesh-peptone-gelatine. The later researches referred to by Flügge are those of Bumm.[2] This author asserts that the "gonococcus" of Neisser does not grow in *bouillon* or upon flesh-peptone-gelatine. He has, however, succeeded in cultivating it upon blood-serum, and especially upon human blood-serum—obtained from the placenta of a recently delivered woman.

The conclusions of Bumm are pretty generally accepted by bacteriologists. And a careful perusal of his work has convinced me that the inference of the experimenters who preceded him, including myself, that the micrococcus obtained by inoculating *bouillon,* or flesh-peptone-gelatine, with gonorrhœal pus, was identical with the coccus seen in the pus-cells, in stained preparations from the same source, was a mistake. This inference was a very natural one, and seemed to be justified by the state of our knowledge at the time it was made; but we have learned much during the past three years. By the application of Koch's admirable "plate-method" for the isolation of microörganisms, Rosenbach has shown us that no less than four well-defined species of the genus *micrococcus* are to be found in the pus of acute abscesses—sometimes separately and sometimes associated. Bumm, also, has succeeded in isolating no less than five distinct species from gonorrhœal pus, and believes that one or other of these was present in the cultures of those experimenters who have reported successful results in the cultivation of the "gonococcus" in media, which he has found not to be suitable for the growth of the true *micrococcus gonorrhœa.*

Neisser, himself, succeeded in cultivating a coccus upon flesh-peptone-gelatine which he supposed to be identical with his "gonococcus," but which Bumm thinks was a non-pathogenic micrococcus which he has obtained from the same source, and which has a citron-yellow color.

One of the most common cocci found by Bumm in gonorrhœal pus, and one which he has frequently obtained, as well, from the normal secretions of the healthy vagina, is a milk-white diplococcus, "probably identical with that cultivated by Bokai, Eklund, and Platonow." This was very probably the coccus which appeared in my cultures, and which served for my inoculation experiments. Upon flesh-peptone-gelatine I found that this coccus formed a shining milk-white layer with a well-defined margin. It was material of this kind which I introduced into my own urethra with a negative result.

According to Bumm, the true "gonococcus" grows very slowly upon blood serum as a thin, often scarcely visible layer, of a grayish-yellow color when seen by reflected light, having a smooth, moist surface, and margins which diffusely overlie the culture-medium, and do not produce any liquefaction of the same.[1]

It is evident from what has already been said that I no longer attach any importance to the negative results obtained in my inoculation experiments, and the main object of the present note is to record this statement. My conclusion, announced in my first paper, that the coccus which I had repeatedly obtained from gonorrhœal pus was identical in its morphology and biological characters with *micrococcus ureæ* is sustained by my own subsequent experiments, and I believe it to be entirely correct; but my inference that this coccus is identical with the "gonococcus" found in the pus-cells was a mistake. This mistake arose with me, as with others—Neisser, Cameron, Bockhart, Bokai, Sattler, Arloing, and others—from the fact that I discovered only one species of micrococcus in my microscopical examinations of stained preparations of gonorrhœal pus, and inferred that the coccus which appeared in my cultures was identical with this. It is evident, however, that if this coccus, which was present in great numbers, would not grow in the culture-medium employed by me, and another coccus was present in the same material in small numbers, the latter could have been easily overlooked, but would nevertheless appear alone in my cultures, by reason of its ability to multiply in the culture-medium employed.

Neisser has claimed that the morphological characters of his "gonococcus" are sufficient to identify it; yet he himself, according to Bumm, was mistaken in supposing that he had cultivated it upon flesh-peptone-gelatine; and Bockhardt must have made a similar mistake, as his paralytic patient was inoculated with a fourth generation of a coccus, cultivated upon this material.

In my paper above referred to (THE MEDICAL NEWS, October 18, 1884) and in my book (*Op. cit.*, p. 307), I insist that Neisser was mistaken in claiming that his "gonococcus" has distinctive morphological characters. This opinion is justified by the development of our knowledge of micrococci, and is sustained by the extended observations of Bumm. This author says:

"Later and more extended observations have taught me that the biscuit form is not specific for the gonococcus, which shares it with a considerable number of other microörganisms, which consist of two hemispherical por-

[illegible]

Erkrankungen, Wiesbaden. 1885.

[1] Op. [illegible], p. 1[illegible]

tions separated by a cleft, and often correspond with the gonococcus even in the most minute details of form." (*Op. cit.*, p. 16.)

It is a little difficult to understand how Bumm can be so positive that he, himself, has cultivated the true "gonococcus," when there are no morphological characters by which it can be positively recognized. His identification of the slow-growing coccus above described, which forms a thin grayish-yellow layer upon blood-serum with the "gonococcus" as seen in the pus-cells, no doubt depends chiefly upon his single inoculation experiment. In this experiment a *second* culture upon blood-serum was introduced into the urethra of a female, whose genitalia and urethra were in normal condition, and had been carefully searched for gonococci, with a negative result. On the third day after the inoculation burning pain occurred upon passing water, and already gonococci were found in the epithelium of the urethra. A characteristic urethral gonorrhœa, the acute stage of which lasted for three weeks, followed. The presence of gonococci during the entire duration of the urethral discharge was demonstrated by daily examinations.

The same criticism may be made in this case as in the inoculation experiment of Bockhart. Thus Flügge says: "A second successful inoculation experiment has been made by Bumm upon the healthy mucous membrane of the urethra of a female, with a second culture grown upon blood-serum. In this instance, also, notwithstanding the fact that no pus-cells were found in the culture upon microscopical examination, we cannot entirely put aside the objection that perhaps the cocci in the urethral discharge were simply carried over, especially as the first transference upon the artificial culture-medium was made with relatively large masses."[1]

In view of this objection we must admit that the experimental evidence in favor of the etiological relation of the gonococcus to the infectious disease with which it is associated is not entirely satisfactory. But we have evidence of a different kind which, taken in connection with the present state of knowledge relating to the rôle of parasite organisms in infectious diseases, makes it appear almost certain that the infectious nature of gonorrhœal discharges depends upon the presence of this coccus. That it is constantly present in such discharges has been demonstrated by the extended researches of numerous observers; and Bumm, the author above quoted, has shown by a careful study of a considerable number of cases of gonorrhœal conjunctivitis, that the epithelial layer of the inflamed mucous membrane is invaded by "gonococci," and that they even penetrate to the subepithelial connective tissue.

Post Scriptum.—In the first number of the *Centralblatt für Bacteriologie und Parasitenkunde*, which has just come to hand, I find a review of the second edition of Bumm's work above referred to. In this the statement is made that Bumm has made two successful inoculation experiments, in the urethræ of healthy females. One with a second culture, the other with a twentieth culture, grown upon human blood-serum. The second experiment has evidently been made since the publication of the first edition of Bumm's work. As the culture used is said to have been the twentieth, the objection made with reference to the previously recorded experiment, and to that of Bockhart, can no longer be made, and we may at last admit that there is satisfactory experimental evidence of the etiological relation of the "gonococcus" to the infectious disease in which it is constantly found.

THE SURGICAL TREATMENT OF DISEASES OF THE GALL-BLADDER.[1]

By JUSTUS OHAGE, M.D.,
OF ST. PAUL, MINNESOTA.

Concluded from page 206.

There are now before the profession three recognized modes of operating for the removal of liquid or solid pathological contents of the gall-bladder.[2]

1st. Cholecystotomy (natural), as originally proposed by Marion Sims and performed by Lawson Tait. This consists in opening the abdomen, incising the gall-bladder, and stitching it to the abdominal wound after emptying it of its contents, leaving a fistula behind which may or may not, according to circumstances, at variable periods close. This operation may, if the condition of the parts forbids primary suturing, as in my first case, (see Case I.) be done *à deux temps*.

2d. Cholecystotomy (ideal), advocated and successfully performed by Bernays.[3] This consists in opening the abdomen, emptying the gall-bladder of its contents by an incision, and after closing this by sutures, in dropping the gall-bladder back into its place, leaving it free from the abdominal wall.[4]

3d. Cholecystectomy, Langenbuch's operation. This means the complete extirpation of the gall-bladder with its contents.

Of the first operation—let us call it, according to Bernays, natural cholecystotomy—there are forty-nine cases on record up to date; performed by twenty-five different operators, with eleven deaths and thirty-eight recoveries, making a death-rate of twenty-three per cent. It is but fair to state here that in taking this average we must consider that Lawson Tait's twenty-one cases all recovered.[5] This

[1] Read before the Ramsey County Medical Society, St. Paul, Minn.

[2] Aspiration of the distended gall bladder (Albert, loc. cit.); or introducing a trocar, leaving the canula *in situ*; or cauterizing through the abdominal walls by the continued application of caustics to excite adhesive inflammation (Huter, Grundriss d. Chirurgie, 1883, ii. S. 195), are procedures unsurgical, dangerous, and unsatisfactory, and ought to be abandoned.

Winiwarter's "Cholecystenterostomy," by which he establishes a communication between the gall-bladder and bowel, claims our consideration only as a surgical curiosity.

[3] Weekly Med. Review, Oct. 31, 1885.

[4] Allow me at this point to protest against naming the opening of a cholecystic abscess which has formed firm adhesions with the abdominal wall a cholecystotomy. This is no more a cholecystotomy than a nephrotomy is an incision into a lumbar abscess which communicates with the kidney. They are simply onchotomies, incisions into abscess.

[5] London Lancet, Feb. 13, 1886.

... int in favor of the operation, at the ... ence have in regard to recovery.

Another point is that the organ is not removed but placed in such a position that, should the disease return, a second operation would be comparatively free from risk.

These are the two strong points in its favor. The objections to it are that recurrence of the disease is probable, it being known that the gall-bladder itself is the place where gall-stones chiefly form,[1] and the only place where they enlarge.[2] Here they have a place of rest, indispensable to their growth, while in the ducts, especially in the hepatic, the currents of bile would soon sweep them away.

The formation and presence of a biliary fistula are in themselves sources of danger and annoyance. This is offset by Tait, who claims that after all his operations the fistulæ finally closed in every instance. To what extent this is the case with other operators I am not able to state, as the statistics give insufficient data in regard to this very important point. König,[3] after stating that in his and Kocher's case the fistula closed, admits that in other cases where a relapse occurred the stones perforated the intestines.

Of the three operations it is the easiest to perform, and this alone will probably induce its performance as much or more than anything else which might be said in its favor.

The second operation, cholecystotomy (ideal), has, so far as I can learn, been performed five times up to date.[4] The results are—three recoveries, Bobb's, Courvoisier's, and Bernay's; and two deaths, Meredith's, and one reported by Tait. A mortality of 40 per cent.

Bernay's success is due to his masterly performance, so is Courvoisier's, while Bobb's is rather "post hoc." Of Tait's anonymous operator's case no particulars are known. Meredith's case[5] died in forty hours from suppression of urine, and although several ounces of bile were found in the peritoneal cavity, the stitches in the gall-bladder, he claims, were intact!

There is no doubt that this operation is indeed ideal. It leaves the liver non-adherent to the abdominal parietes, it restores the gall-bladder to its original place, and does not agglutinate it to the abdominal wall to interfere with the free mobility of the liver. It leaves the patient, after curing him of his present disease, in as natural a condition as he was before—a fundamental law in conservative surgery—but great as these advantages are we find reasons which fully balance them. In the first place it gives no more security against a recurrence of the disease than the first operation, and if a relapse occurs the whole operation has to be repeated, which, as its mortality shows, is certainly not without danger.

Tait[6] draws attention to this fact and, although Bernay's, in a reply,[1] ably defends his position and asserts that to reopen a gall-bladder after Tait's method is as risky and difficult as after his own, the fact still remains that it may be necessary and the patient be compelled to run the same gauntlet once more.

The high rate of mortality seems also to speak against it (40 per cent.), although I must admit that, in all probability, if the directions of Bernays, especially his mode of suturing, are carried out, the death-rate would greatly diminish, as it does in all operations that are but in their infancy, and where technical improvements are continuously made. At any rate, ideal cholecystotomy deserves a place among recognized surgical operations.

The third operation, cholecystectomy or the complete removal of the gall-bladder, was first proposed by Langenbuch, of Berlin.[2] It has so far been performed nine times with eight recoveries and one death, a mortality of 11 per cent. Langenbuch[2] performed it five times with one death. M. Thiriar[4] twice, both times successfully; Courvoisier[5] once, successfully, and myself[6] successfully; mine being the first case of its kind in the United States.

These nine cases are well authenticated, and at once their low mortality strikes the observer favorably. Nine cases, with eight recoveries and the one death, the result of an accident—an undetected perforating ulcer of the cystic duct! This is certainly a triumph of modern surgery, where nine lives would have perished but for surgical interference. I do not deny that by the two other methods this same result might not have been obtained. But here it was obtained, in fact, by cholecystectomy, an operation which Lawson Tait persists in calling "intrinsically absurd."

The chief point of consideration now, after comparing the results of the three kinds of operations and finding the smallest mortality in cholecystectomy, is this: Is life compatible without the existence of the gall-bladder, or not? I think it is. I consider the gall-bladder merely an organ "par complaisance," less so than the urinary bladder and rectum, more so than that rudiment, the processus vermiformis, without which man would be certainly better off than with it. In some of the mammalia, the deer for instance, the gall-bladder is naturally absent, and there are numerous cases on record where in man it was so obliterated by disease that it was of no use whatever. Parkes's[7] case is an illustration of this, and my second case, where a calculus had obstructed the cystic duct and where the greatly enlarged gall-bladder was filled with a clear, transparent liquid, without the admixture of a drop of bile, and had been so to all appearances for years, rather forcibly prove the supposition that the gall-bladder is not essential to life, and its removal not absurd. But above all, the results of the cases

Northwestern Lancet, Nov. 1, 1886
American Journal of the Medical Sciences, 1885.

of cholecystectomy conclusively show the correctness of this supposition. These are well proven, undisputed facts which cannot be overthrown by any theory, no matter how philosophical.

Let us now compare my two cases as to their results. We may, for sake of shortness, call the cholecystotomy Case I., the cholecystectomy Case II. They are analogous in that in both of them the dislodgement of gall-stones and the obstruction they caused indicated the operation. In Case I. the disease had lasted for twenty years, the obstructing stone was lodged in the common bile-duct, in consequence of which there were icterus, bile resorption, and empyema of the gall-bladder. In Case II. the disease had lasted over three years, the obstructing stone was in the cystic duct, while the hepatic and common ducts were free, consequently no icterus but hydrops of the gall-bladder.

In Case I. there were extensive adhesions, caused by inflammatory processes during a long illness, which prevented separation of the gall-bladder from the surrounding mass, making cholecystectomy impossible. In Case II. no such pathological adhesions existed.

In Case I. the fistula did not close until the sixth week. In Case II. there was no fistula at all, and recovery was complete in less than two weeks. In Case I. a relapse may take place, although it would not be of serious consequence. In Case II. no relapse can take place.

Both patients are, in regard to comfort, ability to perform all their work, and complete recovery, perfectly alike; in both all organs act naturally in every respect; in both the processes of digestion, assimilation, and excretion are perfectly normal. Neither is aware of discomfort of any kind. Of the two, Case II. made the quickest recovery. I saw both patients within the last few days; they are in perfect health, do all their housework, and the fistula in Case I. remains closed.

The decision, which of these different methods is the best, the safest, and which promises most good for the patient, I would modestly lay before the tribunal of the profession. Let the given facts and statistics bear proper testimony pro or contra. I have endeavored to review the subject impartially and unbiassedly. In all probability, all three operations will be recognized and performed. Which one will in any case be preferred will depend upon the circumstances of the case, and the judgment of the surgeon who operates.

Surgical interference is indicated in cases of repeated paroxysmal pain in the region of the gall-bladder, when there is good proof that it is caused by the passage of gall-stones. It is also indicated in *all* cases where from this cause obstruction has occurred, especially if this obstruction is in the hepatic or common duct, preventing the bile from entering the bowel, producing reabsorption and icterus. Here the indication is vital, and an operation must not be delayed too long. Operative interference is extremely urgent if rupture of the gall-bladder has taken place and peritonitis set in.

I would like to call attention to the fact that "shock" is not a contraindication for laparotomy in perforative peritonitis. Shock is maintained often by the extravasated material which excited the peritonitis, and with the removal of this matter by disinfection of the abdominal cavity the shock disappears. Within the last year I have twice performed laparotomy, and washed out the peritoneal cavity with a 1 : 4000 corrosive sublimate solution for acute septic peritonitis. It was once caused by the bursting of a tubal abscess,[1] and once by a sloughing ovarian tumor[2] (axis rotation). Both patients recovered.

In regard to which method to choose if operative interference is decided upon, I submit the following propositions: In old, decrepit subjects, where the disease (cholelithiasis) is probably ended, over fifty years of age, or where extensive pathological adhesions exist, or where there is doubt in regard to the patulency of the ducts, I would favor cholecystotomy. In young, healthy subjects, where the stone formation is probably not yet ended, where no other but the physiological adhesions exist, or where pathological ones, if present, are easily separated without much hemorrhage, where the ducts to a certainty are patulous and unobstructed, I would favor cholecystectomy.

But if, in spite of the removal of the gall-bladder, a stone should form and enlarge sufficiently to obstruct the common duct, what ought we to do then? We should have to reopen the abdomen, and either remove the stone by an incision into the walls of the duct, or crush it with padded forceps and work the fragments into the duodenum, as Tait has done.[3]

Considering the softness and friability of gall-stones, this can be done without injury to the walls of the ducts, and would be no more dangerous than a second operation after the other two methods, but its necessity would be far more remote.

It would be otherwise if obstruction of the common duct were caused by a neoplasm—cancer, for instance—but even then there would not be a great difference. Besides such a complication being fatal under any circumstances and after any of the three methods, there is also a limit to the ability of distention of this "safety bag," as Bernays calls the gall-bladder. The limit being reached, rupture must necessarily take place and death follow. Yet an operation, somewhat similar to Winiwarter's cholecystenterostomy, might be performed, and a communication established between the dilated common duct and the colon.

Bernays has suggested the same, and Dr. F. Gaston,[4] of Atlanta, Georgia, experimented on dogs in regard to the feasibility of this plan. His experiments are not yet concluded.

In regard to the diagnostic symptoms of gall-stones and of obstructions caused by them, I refer to the text-books which dwell sufficiently on that point. I will mention only those signs which are of most practical value.

If a patient has for some time suffered from repeated attacks of paroxysmal pain referred to the

[1] N. W. Lancet, iv., No. 16. [2] Ibid., v., No. 1.
[3] The Medical News, Aug. 1884, p. 123.
[4] Gaillard's Journal, 1884.

right hypochondrium and extending into the right shoulder, and after these attacks has been jaundiced, we may by exclusion arrive at a probable diagnosis of gall-stone disease. If no icterus has appeared the diagnosis is more uncertain. If, then, after such attacks the stools are examined by liquefying them with water and pouring them through a sieve, and facetted gall-stones are found, the diagnosis is positive. When obstruction has occurred the pain will remain more constant. If the obstruction is in the common bile-duct, jaundice and enlargement of the gall-bladder will soon be noticed, if in the cystic duct, enlargement without icterus; if in the hepatic duct (very rare), icterus without enlargement. If the obstruction is in the common or hepatic duct the absence of bile in the stools will make them clay-colored; if in the cystic duct, the color will be natural. If in the right hypochondriac region a tumor is noticeable which follows the respiratory movements of the liver, and if the other symptoms of gall-stones have singly or conjointly preceded the appearance of this tumor, it is most probably a distended gall-bladder due to obstruction. Sometimes the diagnosis is easy if the examination is carefully made; at other times, especially if the obstruction is in the cystic duct and icterus is absent, it may be very difficult. At any rate, an explorative incision, which is safer and more satisfactory than aspiration or puncture, is indicated where the symptoms are such that surgical interference is necessary. The incision must be large enough to permit free inspection of the lower surface of the liver, and to admit the hand into the abdominal cavity that all the parts in question may be accurately palpated and defined. If the diagnosis is verified, the other steps of the operation, whichever method the operator chooses, follow directly upon the exploratory incision. If the case should turn out to be unfit for operation no harm is done, the dangers of an explorative incision, properly performed, are almost nil, but it will clear an otherwise obscure diagnosis, and thus may prove to be of great benefit to the patient.

The operation should be performed under strict antiseptic precautions. Tait and Bernays are apparently against antiseptics, and yet, according to their own statements, thoroughly aseptic. They are scrupulously clean, and cleanliness is the cardinal rule of antiseptic surgery. He who thinks that by the use of corrosive sublimate, carbolic acid, iodoform, etc., he has done his duty in regard to antiseptic operating is sadly mistaken if he excludes cleanliness.

In private hospitals and wards absolute cleanliness without chemical antiseptics may be sufficient; not so in general hospitals, where all kinds of cases are admitted. It is not too much extra work to carry out the details and principles of antiseptic surgery, and a human life is too high a price to pay for the neglect of precautions which undoubtedly add greatly to the safety of patients.

The operation must not be done too late. If the circumstances of the case demand surgical aid, the sooner the operation is done the better. There is nothing gained by waiting. Hepatic abscesses may form and result in death, rupture of the bile-ducts or gall-bladder may take place at any time and excite a fatal peritonitis, and the strength of the patient will certainly not improve during the progress of the disease. Irremediable damage may be done by waiting too long, and the life of the patient be sacrificed.

Within the last few years I have seen in consultation more than half a dozen cases of gall-stone disease which terminated fatally, where an early operation would have saved life. The saddest case I recollect was that of a lady who died in the prime of life, after an illness of a few months, from hepatic abscess due to gall-stone impaction.

That some few recoveries do occur where the obstructing stones ulcerate through the abdominal walls or into the intestines, proves nothing against early operating. Even if recovery takes place, although only after much suffering and risk to the patient, it is rather a *testimonium paupertatis* to the attending surgeon.[1]

The diseases of the gall-bladder belong to the surgeon, and only through him can speedy and permanent relief be obtained. That the profession at large is unacquainted with these facts is no wonder. The literature on the subject is very scanty. With the exception of the few articles referred to above, little or nothing is said about it in the text-books. The whole subject is so novel, and the custom to treat these diseases by internal medication—no matter how fruitless—so incorporated in a large proportion of the profession, that I am afraid it will take some time yet before the importance and success of surgical treatment of these diseases are properly recognized. To aid toward that end is the object of this paper. If through it the impetus to renewed investigation and advance is given, by which life may be saved and suffering relieved, the author will be amply repaid for the work and labor he has bestowed upon this subject.

[illegible] Phila. Med. [illegible]

MINOR SURGERY AT THE CHAMBERS STREET BRANCH OF THE NEW YORK HOSPITAL.

By G. B. PHELPS, M.D.,

Surgeon to Out-Patient Department, Chambers Street Hospital

The Out-Patient Department of the Chambers Street Hospital is for the treatment of surgical cases only. There is a class for pathological cases and fractures (except those of the bones of the hand and foot), under the care of Dr. Powers, in which about eighteen patients are treated daily; one for traumatic cases and the fractures above excepted, where about one hundred and thirty-six patients are treated daily under my supervision; and a class for venereal diseases, under Dr. Fuller's care, where about sixty-five patients are treated on Monday and Friday evenings.

As a rule, the patients pay very little regard to

[1] [illegible] Med. [illegible] where incomplete obstruction existed for eight years, the patient having had *tolerable* health until a few months before *death*.

cleanliness, and many are almost tramps. The dispensary assistants are, besides two of the house-staff, either third-year students or recent graduates. The work in the traumatic class is done almost wholly by gaslight. These conditions are mentioned to show under what circumstances the work is carried on.

Fresh cases have the surface about the wounded part washed with soap and water, and, if covered with oil, cleansed with ether. The wound is then thoroughly irrigated with a 1 : 1000 solution of bichloride of mercury. If there is hair about the part, this is removed with a clipping-machine or a razor.

Incised and lacerated wounds of the scalp, after checking the hemorrhage by clamping and tying any bleeding points, or by pressure, are sutured with catgut, without drainage, unless the wound is very extensive. Contused wounds are similarly treated, unless there is much contusion of the edges, when the wound is packed loosely with wet bichloride gauze. Over the wound a compress of plain absorbent gauze, freshly wrung out of a 1 : 1000 bichloride solution, is placed, with a small amount of boracic acid ointment (twelve and a half per cent. boracic acid in cosmoline) spread on it just over the wound. Over this a thin layer of absorbent cotton is placed and bandaged on. Such cases report in twenty-four hours, but the dressing is not changed unless it is soiled or there is pain. These wounds usually do perfectly well, but a dressing can be rarely left on more than four days, because it becomes soiled, many patients reporting with bandages almost black. For three months there has not been a case of cellulitis of the scalp that has arisen while the patient was under treatment, though primary union is not always obtained, in some few cases there being slight suppuration. These wounds are then opened and allowed to granulate.

In wounds of the fingers an effort is made to save as much of the member as possible, and surprising successes are often obtained. Wounds that admit of suture are drained with a few horsehairs or catgut strands. A dressing similar to that for scalp wounds is applied. The advantage of such a dressing over a dry dressing of either iodoform, iodoform gauze or bichloride gauze, is that it feels more comfortable, and that when it is removed it comes off without sticking or causing pain, while a dry dressing is usually so firmly held by the slight bloody discharge that it requires some time and much trouble to remove it painlessly. In this dressing we depend upon the bichloride for antisepsis, the boric ointment being used to prevent sticking. Iodoform we do not use in this dressing, knowing that we have a reliable antiseptic in the bichloride of mercury, the only indication for the addition of iodoform powder being to relieve pain. But an aseptic wound causes little pain, hence the iodoform, which is expensive, is omitted.

From this dressing I have seen only one case of eczema, but the majority of our cases are wounds of the hand, in which the skin is tough. In wounds in which there is much laceration, we think it very important, either to make counter-openings for drainage, if there is a large pocket, or simply to pack with moist gauze where this is small.

Divided tendons and nerves are sutured with fine catgut, and many excellent results follow. Ether is given in these cases, as a rule, for before operating it is often impossible to know how extensive a wound must be made. A heavy dressing is applied, and a splint to keep the parts at rest in extension or flexion, as the case requires.

Cellulitis has developed while the patient was under treatment very rarely, in only two cases in three months; but a small number apply for treatment with cellulitis already well marked. The history in these cases, almost always is, "I didn't think it would amount to anything, and went to the druggist, who put this bit of plaster on." Too much cannot be said against applying strips of plaster to fresh wounds. If a bandage is not needed, we put a small compress of gauze over the wound, and hold this in place by means of plaster. If a cellulitis is just starting, and there is very little tension, or no particular point of pain, the original wound is opened, thoroughly washed with 1 : 1000 bichloride solution, and the parts then wrapped in a large compress wrung out in 1 : 40 carbolic acid, a piece of rubber tissue placed over this, and a bandage applied, leaving one end open so that the patient can, from time to time, pour on a small amount of the carbolic solution. The carbolic solution is preferred to bichloride, as the latter, applied as a wet compress over a large surface, is very apt to cause an eczema. From the carbolic acid solution I have seen three cases in three months in which large blebs formed, and the epidermis was loosened from a large part of the hand, but this accident is very rare. For women and children 1 : 60 carbolic solution is used. If the cellulitis has gone further, and there is evidence of pus, or there is much tension, incisions are freely made. Where possible, counter-openings are made, and a small rubber drain inserted. The treatment of cellulitis is considered of the greatest importance, and free and early incisions are demanded in the interest of the patients. We never wait for distinct fluctuation, or "pointing."

In the treatment of this trouble cocaine is of the greatest value, and, when properly used, always gives admirable results—that is, injected *into* the skin (*not* beneath it) at the point of incision, or beneath the skin on the proximal side of the point to be incised. For example, to open an abscess on the palmar surface of the distal phalanx, inject about ten or fifteen minims *deeply* into the middle of the palmar surface of the proximal phalanx; then wait two or three minutes before making the incision. These points in the use of cocaine were demonstrated to me by Dr. R. J. Hall.

In one case, five minutes after the injection of fifteen minims of cocaine about the elbow, the patient vomited freely, and three or four others have complained of nausea or faintness after the use of from fifteen to twenty minims. As many patients faint when they first come to the dispensary, either from looking at their own wounds or those of others, it is not easy to know how much effect cocaine had in producing the faintness in these cases.

When wounds are granulating, balsam of Peru on strips of gauze is found to be very valuable in stimu-

lating granulations. Nitrate of silver is sometimes, with advantage, alternated with this. If there is an offensive odor from a sloughing wound balsam will speedily destroy it.

Particular attention is required to prevent granulations from becoming excessive, and when they tend to grow above the cicatricial edge they are removed with a pair of curved scissors, which can be done without causing pain. This is much better than attempting to keep them down with caustics. The bleeding is stopped by pressure, and the ulcer then strapped, if the skin about it is healthy, or small pieces of rubber tissue are placed across the wound, and held in position by a dry compress and bandage. For this purpose rubber tissue is nearly as good as green protective, and much cheaper.

Burns are treated at first with iodoform-ointment (twelve and a half per cent. of iodoform), if not too extensive (as on a hand and wrist), later with an ointment of starch 25 parts, oxide of zinc 25 parts, salicylic acid 3 parts, and cosmoline 50 parts. Some cases do better under powdered subnitrate of bismuth.

Sprains are treated at first with iodoform-ointment, spread on gauze, which is covered with common cotton, *firmly* and smoothly applied. If at the wrist, a dorsal splint is used. Iodoform certainly relieves pain in these cases very much. The part is kept at rest about four days, and then, if pain persists, or there is much effusion, Paquelin's cautery is lightly applied, and the part bandaged after rubbing on a little vaseline. The cautery is used at a dull red heat, and applied so as to produce a uniform redness over the joint, and should leave almost no scar. Iodine ointment (U. S. P.) is used sometimes, as a counter-irritant, and to hasten absorption. The tincture is rarely used, as it soon produces a hard, thick layer, so that the next application produces no effect on the parts beneath. We find the actual cautery, as used above, produces excellent results in strains of the back, old contusions, and, especially, in teno-synovitis crepitans of the extensors of the hand when combined with rest.

Of ulcers of the leg many are syphilitic, and in these constitutional treatment is the chief measure in producing a cure. In chronic, indolent, and varicose ulcers every effort is made to promptly place the ulcer in a healthy condition. If the granulations are pale, flabby, and above the surface, they are cut down with scissors and the ulcer strapped for a few days with yellow adhesive plaster. If the base of the ulcer is below the level of the surface of the skin, presenting the "mucous appearance," it is scraped with a sharp spoon and dressed with balsam of Peru. If the skin about the ulcer is eczematous, an ointment of iodoform or boracic acid is applied. These last cases do better when given moderate doses of iron and quinine. At present the following treatment is being reintroduced, as a few years ago it was used here with success. The surface is washed with 1:40 carbolic acid solution and covered with narrow strips of rubber tissue which have been dipped in the same solution. Then a large compress wrung out in a saturated solution of boracic acid is applied; over this, rubber tissue and cotton-line bandage are added, and the dressing is left on from four to eight days.

Patients with varicose veins are advised to wear Martin's bandage.

Chancroids with an active erosive tendency are treated by cauterization with nitric acid and 95 per cent. carbolic acid. The latter causes only slight pain and anæsthetizes the part, but is often too superficial in its action, and nitric acid is then applied to the sore, which is dried and dusted over with iodoform powder, and a piece of absorbent cotton packed into the ulcer. The patient is instructed to wash the parts about the sore daily with water, and then dry them thoroughly before applying iodoform and compress. Chancroids which are simply indolent are touched with cupric sulphate and then dressed, as before mentioned, with iodoform.

Chancres are not cauterized or excised. An "expectant treatment" is followed until the eruption appears, when mercury is given by inunction, the ointment or oleate being used. The stomach is thus undisturbed, and tonics, usually indicated, are readily taken and well borne. When the inunctions are commenced the patient is made to use a tooth-brush and castile soap to keep the teeth clean. In addition a gargle of chlorate of potash is given. Unless the precaution of cleanliness is observed the gums soon become tender and bleed readily, but with it, these symptoms rarely develop.

The majority of patients being forced to keep at hard work no attempt is usually made to abort a bubo. In some few cases when rest can be obtained pressure is applied, and in a majority of cases suppuration is avoided. As soon as there is redness and much pain in the bubo, an incision is made without waiting for signs of fluid to appear. The incision is made after the injection into the skin of cocaine, and very little pain is felt. The incision is a free one, parallel to Poupart's ligament, and opens the whole of the tissues involved. The finger is then introduced into the incision, and the spongy mass thoroughly broken down and enucleated, a steel curette being frequently needed when the mass is firm. To open freely the pockets on either side of this cut several others are made at angles to the primary incision. The bubo is then packed with iodoform-gauze and heals by granulation.

MEDICAL PROGRESS.

A New Hypnotic.—Dr. Ghillany, pharmacologist to the Vienna General Hospital, has succeeded in preparing an alcoholic extract from the roots of Piper methysticum (kava-kava), which is called "extractum kava depuratum." Experiments made with this drug by some physicians of the hospital proved it to be a valuable hypnotic. In all the cases where it was administered sleep was produced, without any disagreeable consequence; even headache, following generally the exhibition of hypnotics, did not occur. It was given, as a powder, from two to five grains being a dose; or as a suppository containing two grains.—*Lancet*, Jan. 8, 1887.

Diagnosis of Incipient Carcinoma of the Cervix Uteri.—Stratz regards the diagnosis of this condition as difficult, and mentions the usual signs of profuse menstruation, profuse discharge, moderate pains not incompatible with the patient's age, symptoms not extremely grave in themselves, but which may indicate future danger.

While the microscopic examination of a portion of the tissue gives decisive information, there are macroscopic appearances which Stratz describes as pathognomonic. These are:

1. That the diseased tissue is sharply differentiated from the healthy.

2. This difference is especially well marked at the borders in the whole circumference of the suspected portion.

3. The diseased tissue is light yellow in color.

4. On isolated portions of the pathological tissues are small, whitish, glistening kernels.

Decomposition of Hypodermatic Solutions.—It is known that considerable local irritation sometimes follows the introduction of a medicine hypodermatically, and this result has been attributed to the influences of microörganisms contained in the solution used. The conditions under which this influence is exerted have been the subject of an investigation by Dr. Engelmann, whose attention was directed specially to solutions of ergotin. He reports (*Med. Wochenschr.*, No. 39) that by cultivation on gelatine plates he has demonstrated the constant occurrence of microbes in solutions of ergotin of various origin, but that the organisms differed widely in their number and nature. On the whole, he is nevertheless of opinion that ergotin is not particularly favorable to their development, since, after a time, the organisms seem to perish, either through exhaustion of nutriment or other causes. Moreover, the ergotin does not appear to undergo any alteration. Speculating as to the origin of the organisms, he was led to suspect that they might be derived from the water used in dispensing, and upon testing several samples of distilled water obtained from high-class pharmacies, he was astonished at the number of organisms present in them. This state of things Dr. Engelmann considers is attributable to the fact that the vessels used for storing distilled water are not thoroughly cleansed sufficiently often, and thus become a breeding place for microbes. The influence of certain antiseptics, such as carbolic and salicylic acids, glycerine, and mercuric chloride, in preventing the development of organisms in such solutions was tried, but it was found that when used in any admissible proportions they exercise only a limited influence. Dr. Engelmann, therefore, prefers the use, where practicable, of solutions freshly prepared with previously sterilized distilled water.—*American Druggist*, Feb. 1887.

Consanguinity and Mental Unsoundness.—From the physician's point of view, the evidence from the animal world is important. Here there is almost consensus, that, while the effect of "in-and-in breeding" is to intensify *points*, in the long-run it is opposed to vigor of constitution. It is to be remembered that every breeder takes care to exclude any animals with any known morbid tendency, while, on the contrary, in the genus Homo, as Dr. Clouston remarks, there seems to be "a special tendency for members of *neurotic* families to intermarry." The result of this will be that in some portions of the population the offspring of such marriages will show the evil results of it to an unusual extent. And thus we find, that in rural and especially in mountainous districts, where the population is small and fixed, the comparative amount of idiocy is greater than elsewhere. Statistical information is inadequate on the subject: the motion to include it in the census returns of England was rejected "amidst the scornful laughter of the House, on the ground that the idle curiosity of speculative philosophers was not to be gratified." In France the returns have given rise to various estimates (varying from $\frac{1}{10}$ to $2\frac{1}{2}$ or 3 per cent.) of the frequency of consanguineous marriages. Mr. G. H. Darwin came to the conclusion that in London $1\frac{1}{2}$ per cent. of all marriages were between first-cousins, in urban districts 2 per cent., and in rural districts $2\frac{1}{4}$ per cent.

If, now, we ascertain the ratio of idiots and insane patients that are the offspring of such marriages to the total number of patients in the asylums, we will have some means of estimating the results of consanguinity. From quite an extended series of records, it is concluded that the ratio just referred to in the idiot-asylums is from 3 to 5 per cent: hence "*first-cousin* marriages, at any rate, are to some extent favorable to the production of idiot children." But this conclusion must be tempered by the consideration that in a large number of such cases of idiocy and imbecility other causes for this condition are present; and this consideration leads Dr. A. Mitchell to the opinion that "under favorable conditions of life the apparent ill effects of consanguineous marriages were frequently almost *nil*, while, if the children were ill fed, badly housed and clothed, the evil might become very marked." From such facts and figures we may conclude that first-cousin marriages should, as a rule, be discouraged; but that, if a close scrutiny reveals no heritable weakness, neurotic or otherwise, the banns need not invariably be forbidden.—*Science*, February 4, 1887.

Painlessness or Pain in Neoplasms.—Works on surgical pathology rarely refer to this point, although it is really one of the utmost importance, and especially so as the most vague, as well as the most erroneous beliefs are held regarding it, both by the profession and the public. It is said, in effect, that pain is generally slight, or absent, in benign growths, such as lipoma, adenoma, and fibroma, and, on the contrary, is intense and almost constant in those of the malignant class—epithelioma, osteosarcoma, and cancer; but this is absolutely untrue. Benign tumors may be very painful, and malignant ones are occasionally painless. This symptom, then, is as uncertain in diagnosis as in the prognosis, or in indications for treatment. In diagnosticating, when there is no pain, the surgeon as well as the patient is apt to neglect or slur over an examination which other symptoms should make urgent. For instance, a woman has reached the menopause; she suffers from repeated metrorrhagia, more or less excessive, *but from no pain*. The patient objects to an examination; the surgeon does not press the point, and matters drift on until the disease has advanced too far for surgical interference to be practicable. Or, a man has on his tongue a little ulcer which will not

heal, but gives no other trouble; he may or he may not have had syphilis, but the indolence (*indolentia*, freedom from pain) of the little excavation is so strongly suggestive of this disease, that the patient is dosed with iodide of potassium or mercury until the infection of the neighboring glands demonstrates, but too late, its true character. Pain or painlessness are but contingent symptoms; and, whatever the nature of the growth may be, in its inception it is most generally painless, for the simple reason that until it invades sensitive areas it cannot give pain. So far as tumors are concerned—since they have no nerves—pain is an extrinsic phenomenon, but clinically of the utmost importance, for it indicates the invasive progress of the growth, and that the time for operative interference may have already passed away.—*Provincial Medical Journal*, February 1, 1887.

A MOUTH WASH OF SALOL.—Salol is recommended as an excellent antiseptic mouth wash, much preferable to solutions of salicylic acid, as it does not affect the teeth. As it is insoluble in water, it is separated from its alcoholic solution by the latter in the form of minute droplets which adhere to the teeth and gums and exert there a protracted antiseptic effect. It should be dissolved in alcohol, and enough of the solution added to water to make the mixture contain three per cent. of salol.—*Therapeutic Gazette*, Feb. 1.

NEW FORMULÆ FOR ANTISEPTICS FOR INJECTION.—MEUNIER, in the *Bulletin Général de Thérapeutique*, January 30, 1887, gives the following formulæ which he has used successfully upon animals and human subjects:

1.—Iodoform, chemically pure . 1 (by weight).
Lowest vaseline 9

Pulverize the iodoform and add the vaseline slowly, and triturate carefully. Filter through two papers; keep the liquid in a flask of yellow glass, similar to those used by photographers, with ground-glass stopper.

2.—Pure menthol 10
Liquid vaseline 90

Melt the menthol in the vaseline at gentle heat over a water-bath. Filter twice.

3.—Pure thymol 1
Liquid vaseline 200

Prepare in the same manner as menthol.

4.—Phenol, pure 1
Liquid vaseline 100

Prepare as above.

5.—Iodine 1
Liquid vaseline 100

Triturate the iodine at low temperature with the vaseline; filter three times; preserve in yellow, glass-stoppered flask.

6.—Camphor 1
Liquid vaseline 100

Triturate at low temperature with the vaseline, and filter three times. Berzélius's filter papers should be used.

The dosage and choice of a mixture must be determined by the clinician; these substances diffuse rapidly, and considerable doses can be obtained by a few injections; it is not difficult to saturate an organism by this method.

THE DIGESTION OF MILK.—M. REICHMANN, of Warsaw, has recently made several experiments on the digestion of milk in the human stomach. The subject was a young man, aged twenty-two, in robust health. The experiments were made by means of the stomach-pump, with unboiled, as well as alkaline and boiled, milk. The results were as follows: 300 cubic centimetres of unboiled milk are evacuated by a healthy stomach four hours from the time it has been taken, although the regular digestion is completed three hours afterward. Coagulation of the milk takes place about five minutes after ingestion, and does not depend on increase in the quantity of acid, but on another agency, possibly the fermentation of rennet. During the digestion of 300 cubic centimetres of milk, the contents of the stomach show the greatest average degree of acidity (32 centimetres per cent.) at the end of an hour and a half. This acidity is owing, when digestion begins, to the presence of lactic and hydrochloric acids; the latter appears only three-quarters of an hour after the ingestion of milk. Half an hour after taking the milk the quantity of peptones is increased, and remains so for an hour and a half, after which time it becomes perceptibly less. Boiled milk (heated at from 16° to 26° C.) was taken into the stomach; 300 cubic centimetres were digested in two hours and a half; the acid contents of the stomach disappeared in three hours. After the ingestion of boiled milk, peptonization, which in that case is more energetic, begins sooner, and the clots and caseine are not so thick as when unboiled milk is given. Experiments with alkalized milk have shown that alkalization of milk prevents the peptonizing action of gastric juice. One hundred cubic centimetres of milk, alkalized by means of bicarbonate of soda, leave the stomach entirely at the end of two hours. Alkalization does not prevent milk in the stomach from coagulating under the influence of rennet. In conclusion, M. Reichmann says that the result of all his experiments on one person entirely coincided with nine previous experiments he had made.—*British Medical Journal*, Feb. 12, 1887.

COD-LIVER OIL.—M. CARLES, Professeur Agrégé at the Faculty de Médecine of Bordeaux, has recently reaffirmed that the cod-liver oil which is lightest in color is the purest and the most easily assimilated. The deep color frequently seen in cod-liver oil is owing to more or less putrefied livers having been used. M. Hogg, a Paris chemist, had already stated, in a report read before the Academy of Medicine, that the natural oil obtained from the cod's liver is almost colorless and tasteless; that it smells of fresh fish, and that cod-liver oil which is brown in color has been prepared from livers in a state of putrefaction. M. Lesueur, Chef des Travaux Cliniques of the Paris Faculté de Médecine, confirms these statements, and testifies to the superiority of M. Hogg's cod-liver oil obtained in his fisheries off Newfoundland by a process of his own. M. Lesueur states that this oil contains nearly double the active properties of the cod-liver oil generally sold, and that it is free from the disagreeable taste and odor of these oils. Different preparations have been invented to replace cod-liver oil, but without success.—*British Medical Journal*, January 29, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 26, 1887.

LAPAROTOMY IN PERITONITIS.

AT a recent meeting of the Philadelphia County Medical Society, in commenting upon a case of peritonitis in enteric fever, which terminated in recovery, DR. J. C. WILSON urged forcibly the wisdom of laparotomy and free drainage in certain instances of peritoneal inflammation, the result of perforation of the bowel in this disease. In the case which he reported there was evidently local peritonitis in the right iliac fossa, with slight extension to the general surface, which a judicious treatment allayed. It was, however, in the cases of sudden collapse, with evidences of intense and general peritonitis, that operative interference was urged, as the only possible means of saving the patient. In perityphlitis, with perforation and general peritonitis, laparotomy has been successfully performed, and the operation seems quite as reasonable in similar conditions arising in typhoid fever. It is true that in the perforation which occurs in the second week, the result of the separation of a deep slough, the state of the patient is, as a rule, most unfavorable, for it is the general experience that the accident happens most often at this stage in very severe cases; still, this is not a valid objection when the operation holds out the only possible hope of relief, and is not itself a very serious danger. In those rare cases of perforation which occur late in the disease, sometimes in the period of convalescence, owing to errors in diet, the prospects of success would be greater as the state of the bowel is more favorable. The success which has attended the practice of opening and draining the abdomen in cases of acute peritonitis from other causes certainly warrants the adoption of similar measures in this grave complication of typhoid fever.

When a peritonitis has subsided, the patient may experience serious trouble from the adhesions which form between the intestines, or between the coils and the parietal peritoneum. These after-symptoms may be so severe as to demand operative interference, as in a case reported by GEORGE W. GAY, in the *Boston Med. and Surg. Journal*, of January 13th. A lad of fourteen was seized, on the 27th of August, with pain in the abdomen and tympanites, for which morphia had to be freely given. Then a tumor, three inches in diameter, appeared below and to the right of the navel. The fever was moderate; the vomiting not excessive, and the bowels were only constipated for a few days, and, subsequently, became loose. The tumor increased for a week, then gradually diminished, and the pain disappeared. Dr. Gay saw the patient about two months after the attack. The pain had returned in the same situation, and was worse than ever, but there was now no tumor, only a little fulness and tenderness at this point. He had lost much flesh, and during peristalsis the intestinal coils could be plainly seen, and the pain was then much worse. It seemed clear that the intestines were adherent to the abdominal wall, and on the fourth day of the relapse the lad's condition was so deplorable that laparotomy was advised. The intestines were found to be attached to the parietes over a space four or five inches in diameter, corresponding to the sensitive spot on the surface. The adhesions were soft and readily separated, except at one place where they were quite firm. The pulse and temperature were normal on the third day, and six weeks after the operation the patient had gained in flesh and strength, was up and about, and feeling quite well.

This was a very exceptional case, as it is rare to have serious symptoms from limited adhesions, and even extensive conglutination of the coils may take place without interfering with the intestinal functions.

In the January number of the *Annals of Surgery*, there is an excellent review of the surgical treatment of peritonitis, and there are seven cases noted of operative interference in non-traumatic perforation of stomach and intestine, all of which were fatal. This is not a very hopeful record, but we find that the operation was delayed from three to ten days—too late to be of any service.

SUDDEN DEATH IN PLEURISY.

THIS subject has been carefully studied by WILSON FOX in England, LICHTENSTERN in Germany, and more recently by WEILL, of Lyons, whose communication appears in *Revue de Médecine* for January, 1887. The last writer reports a case of serofibrinous pleurisy of moderate extent in which death occurred on the twenty-fifth day, and the

autopsy showed fibroid degeneration of the heart. This, with a case of Hayden's, in which there was fatty heart, are the only instances in which myocardial changes were found. A more common cause of sudden death is thrombosis or embolism of the right heart and pulmonary artery, of which Weill has collected nine observations. The compression of the lung and the direct pressure of the exudation on the heart are circumstances which favor clotting in the chambers. In six cases there was acute œdema or congestion of the lungs, most intense on the side opposite to the effusion, but it is not always possible to say whether this was an ante-mortem change. Acute pericarditis has been found in one case, and in two the effusion perforated the lung and the patient was choked by the amount of fluid which entered the bronchi, an accident which is more likely to occur in empyema than in simple pleurisy. In three cases the autopsy showed no changes to account for the sudden death.

The author is not inclined to place much importance on deviation of the heart, torsion of the vessels, and bending of the inferior cava as causes of sudden death in pleurisy. The rectangular bending of the inferior cava, caused by the deviation of the heart, which Bartels and Fränkel have seen in several instances, has not, so far as we know, produced any of the symptoms which might be expected to follow gradual occlusion of this vessel. The theory of capillary embolism of the brain, advanced by Vallin, is regarded as hypothetical.

Sudden death may occur in any form of pleurisy, acute or chronic, progressive or stationary, serous or purulent, and as often in right-sided as in left. A movement or effort, not necessarily sudden, has usually preceded the accident. Occasionally there are preliminary symptoms, attacks of dyspnœa, or of syncope, or of irregularity of the pulse. Very often, however, the patient has been doing well. Treatment is usually out of the question, but a knowledge of the occurrence of this event makes us more ready to adopt, in cases of large effusion, the prophylactic measure of aspiration. In a case which occurred not long since under our own care, the patient, a woman, died on the third day after admission to hospital. There was moderate effusion on left side, displacement of the heart to the right, but no twisting of the inferior cava; except slight myocardial changes, there was nothing found to explain the sudden death.

In two other conditions in pleurisy sudden death may occur. After incision for empyema patients have died during the process of washing out the pleura, possibly from shock; and in these cases, so far as we remember, there have not been any lesions to account for death. Then during aspiration in ordinary pleurisy, particularly toward the close, syncope may occur and prove fatal. This seems more likely to happen when too much fluid is drawn off at once, but we have seen serious symptoms follow the removal of comparatively small quantities, and it is a contingency to be borne in mind. In aspirating weak patients the recumbent posture at the edge of the bed is preferable to the sitting position usually employed.

Although we cannot say that the study of this condition enables us to determine in what class of cases, or even under what circumstances, this accident is likely to happen, yet a knowledge of its possibility should make us more careful in the management of pleuritic effusion; particularly when there is much displacement of the heart.

THE INDUCTION OF LABOR BY ELECTRICITY.

THE fact that an electrical current is capable of exciting muscular contraction, and the knowledge that such contraction, once fairly established in a pregnant uterus, is likely to end by the expulsion of the uterine contents, have led many to look upon electricity as the best means, at least theoretically, by which to induce labor. Practical experiments, however, have failed to sustain this opinion. Electricity has been applied to the pregnant uterus with both electrodes in the vagina, with one in the vagina and the other on the abdomen, and again with both electrodes externally, with the result, it is true, of inducing labor, but only with such time and trouble as to render this method unavailable in general practice.

The latest contribution to the study of the subject can be found in the *Centralblatt für Gynäkologie*, in which DR. LITSCHKUS describes two cases of labor, induced by electricity, both electrodes being placed upon the abdominal walls. In one case eleven applications of a faradic current, lasting about fifteen minutes, and distributed over eight days, finally brought on labor. It the other case, six applications, during five days, resulted in a dilatation of the os sufficient to admit two fingers, when the dilatation was artificially increased, and the child delivered by podalic version.

It cannot for a moment be supposed that a busy practitioner could devote a week or more to the induction of labor in any individual, especially when he has at his command means more certain, more rapid, and as little dangerous, if antiseptic precaution be taken, as the external application of electricity.

LUNG SURGERY.

IN connection with recent remarks on the subject of gangrene of the lungs in THE MEDICAL NEWS of November 13, 1886, and on that of the injection of iodoform and ether in our issue of December 18,

1886, it is interesting to note that Arthur Ransome, at the meeting of the Manchester Medical Society, November 3, 1886, reported a case of gangrene of the lung, and four cases of phthisis in which he had employed intrapulmonary injections of iodoform dissolved in ether, in olive oil, and in oil of eucalyptus. Of these various vehicles he thought the last to be the best. In each of the cases of phthisis from two to eight injections had been used, and temporary benefit had been secured in two of them. In one case symptoms of iodoform poisoning appeared, and in one temporary pneumothorax. In the case of gangrene of the lung, hemorrhage from the lung followed the injection.

It would be interesting to know more of the details of these cases, and to be able to determine how much of the effect which follows the injections could be fairly attributed to them. It is not surprising that Ransome found oil of eucalyptus the best vehicle for iodoform in his operation, for it is, in itself, a useful medicament for putrid cavities in the lungs. Ether, as a vehicle, we would hardly expect to be suitable for intrapulmonary injection. The dangers to which we alluded on a previous occasion would, we think, preclude it from serious consideration in connection with disease of the lungs.

MEDIÆVAL NASTINESS.

We have received a volume which claims to be the *American Homœopathic Pharmacopœia*. It does not appear to be published by the authority of any convention or body of men, and we suppose it to be a private effort to meet a commercial demand. We have been very much amused by noticing in it a survival of mediæval remedies comparable to the survival of the strange gar fish of the Chesapeake which remains as almost the sole representative of the monstrous misshapen ganoid fishes which have been swept out of existence by the successive cataclysms of geologic ages. Thus, in this Homœopathic Pharmacopœia uric acid is directed to be prepared from human urine by concentration, or from excrements of serpents; guano is obtained from the accumulated excrement of sea-birds; lava from the overflow of Mount Hecla in Iceland. Hippomanes is a glutinous mucous substance separated from the allantoic fluid or membrane of the pregnant mare, or cow. Lyssin is the dried saliva of the mad dog. Mephitis is the desiccated stinking fluid of the skunk. Psorium is obtained by squeezing the pus from the festering itch eruption of the negro—whilst the dried bodies of the little red lice which render sad the bright summer days of the domestic fly, appear under the more than regal title of Trombidium muscæ domesticæ. Dried fox liver and dried fox lungs, centipedes, wasps, and other things uncanny and unclean seethe and bubble in this witch's cauldron that steams in these later days, not in the darkness of night, but in the full light of a great medical centre.

The Sixteenth Congress of the German Society for Surgery will meet at Berlin from April 13 to 16, 1887. The theme for discussion, fixed upon at the last Congress, will be "Intestinal Occlusion; Peritonitis; Intestinal Perforation, from an Operative Standpoint." Madelung, of Rostock, will open the discussion.

The Sixth Congress for Internal Medicine will meet at Wiesbaden, April 13 to 16, 1887. Leyden, of Berlin, will preside. The following subjects will be discussed: "Treatment of Phthisis," by Dettweiler and Penzoldt; "Localization of Brain Diseases," Nothnagel and Naunyn; "Pathology and Therapy of Pertussis," by Vogel and Hagenbach.

Among the contributions will be papers upon the "Recognition of Pernicious Anæmia," by Lichtheim; "Pathological Anatomy of Tabes Dorsalis," by Rindfleisch; "Experimental Epilepsy," by Unverricht; "Physiological Importance of the Leucocytes Extravasated from the Tonsils and Glands of the Tongue;" "A Respiration-Chair for the Emphysematous and Asthmatic," "Chyluria," all by Rossbach.

The Senate has passed the House Bill entitled "An Act to establish the order of promotion in the Medical Department of the Army," and there is no reason to doubt that it will be approved by the President, and become a law. The Act provides, "That assistant surgeons of the Army appointed under the act approved July twenty-eighth, eighteen hundred and sixty-six, who have served twenty years, shall be nominated and, by and with the advice and consent of the Senate, appointed to the office of surgeon with the rank of major, to date from the completion of such service; and said service shall be estimated as is now done in computing service for longevity pay, except that service under present commission shall be counted from the date of said commission: *Provided*, That no such assistant surgeon shall be promoted unless he has been examined and found qualified for promotion by a duly constituted examining board, in accordance with existing law: *And provided further*, That the whole number of officers in the Medical Department shall not be increased by this act."

What will be the interpretation placed on this Act by the War Department is, of course, impossible to predict, but what the Senate supposed would be the effect is shown by the report printed in another column, from the House Committee on Military Affairs, which is, moreover, of interest historically.

A BILL has recently been introduced into the Pennsylvania Legislature, entitled "An Act to regulate the practice of pharmacy, and the sale of poisons, and to prevent the adulteration of drugs and medicinal preparations in the State." A copy of the bill has not reached us, but, judging from its title, its object is very commendable. We are informed, however, that Section 10 contains the following extremely objectionable provision: "No person duly qualified and registered under this Act, who supplies medicine or advice to such persons as apply to him at his place of business, but who does not go out to visit the sick, shall be required to register as a practitioner of medicine or surgery under any law of the State of Pennsylvania: *Provided*, he does not represent himself to be a physician, nor claim professional fee or reward as such."

The bill professedly has for its object the protection of the community against ignorance in the compounding and sale of drugs, but it inflicts the greater evil of opening wide the door, which, under existing laws is closed, and exposing the community to counter-prescribing by persons entirely uneducated in the treatment of disease. This section should be promptly stricken out. There is no excuse for it, and it is in contradiction to the general beneficent objects of the bill.

DR. JOHN S. BILLINGS has been appointed Lecturer on the History of Medicine at Harvard University for the current academic year.

DR. GEORGE M. STERNBERG read a paper last week before the College of Physicians of Philadelphia giving the results of his investigations upon the thermal death point of pathogenic microörganisms.

THE Kings County, N. Y., Medical Society has appointed a Committee to draft a bill for presentation to the Legislature, placing cocaine on the list of poisonous drugs, and to be sold only on physician's prescription.

DEATH OF M. BÉCLARD.—This distinguished medical man died, in Paris, February 9, 1887, of pneumonia. He was one of the founders of the *Gazette Hebdomadaire*, and President of the Society [illegible]

THE Hoagland Laboratory at Brooklyn, which, it is stated, is to form part of the Long Island College Hospital, has been incorporated, with C. N. Hoagland, Joshua M. Van Cott, the Rev. Dr. Charles H. Hall, Joshua H. Raymond, and Prof. C. E. West as corporators.

REVIEWS.

THE JOURNAL OF COMPARATIVE MEDICINE. Vol. viii., No. 1. January, 1887. Edited by W. A. COSKLEN, Ph.D., D.V.S., and RUSH SHIPPEN HUIDEKOPER, M.D. Philadelphia: A. L. Hummel.

THE contents of this number indicate that a widespread interest has been aroused in this really valuable journal. The papers represent the scientific and practical aspect of comparative medicine in a most attractive way, as shown by the following list of contents: Tapeworms in Birds, by Professor Joseph Leidy; A Comparative Study of Sebaceous Cysts and Cutaneous Horns, by J. Bland Sutton, F.R.C.S., of London; On the Microbe of Rabbit Septicæmia, by Theobald Smith, M.D., of the Bureau of Animal Industry, Washington; Snake Poison from a Chemico-Physiological Point of View, by Professor T. Wesley Mills, of McGill University; Comparative Ophthalmology; Clinical Observations, by L. Webster Fox, M.D., of Philadelphia; Breeding and Feeding, by A. S. Heath, M.D.; Lung Worms in Sheep, by N. S. Townsend, M.D.; "Barsati," or Atrophic Carcinoma, by Richard Burke, V. S., of the Army Veterinary Department, Cawnpore, India. The editorial and case departments contain much important material, and the burning question of contagious pleuro-pneumonia is ably discussed. The journal is as interesting to the medical practitioner as to the veterinarian, and to physicians practising in agricultural regions, who are expected to know something of stock, it contains information of a kind likely to prove of the greatest value.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 11, 1887.

THE PRESIDENT, C. L. DANA, M.D., IN THE CHAIR.

DR. C. L. DANA reported a case of

PACHYMENINGITIS HEMORRHAGICA,

with large meningeal hemorrhage pressing chiefly on leg centre; right hemiplegia, total paralysis of leg, aphasia, hemianæsthesia, convulsions limited to arm and face. Death. Exhibition of specimen.

The patient was a woman about sixty-eight years old, and came into the hospital with complete motor aphasia, and unable to give any previous history. She had no paralysis at first, but three days after admission she had a general convulsion followed by right hemiplegia, total in the leg, and some right-sided anæsthesia. On the second and third days she had a series of brief localized convulsions involving the face bilaterally and the right arm. These were carefully observed. The movements were clonic, beginning in the muscles of the lower jaw. The other peculiarities were these:

1. The pupils remained small during the convulsions. When wider convulsive centres were discharging, as in general epileptic convulsions, the pupils were dilated. It is not probable that in this case there was some uræmic element, because the post-mortem disclosed no sufficient cause for it.

2. The conjugate deviation of the eyes was at first,

and very temporarily, toward the side of the lesion and away from the paralyzed side. The head also was turned toward this side. When this occurs it is ordinarily spoken of as a paralytic deviation. This does not explain it here, since almost immediately the head and eyes were turned strongly to the opposite and paralyzed side.

He suggested that the first deviation was due to an inhibition of the activity of the associated nuclei of the third and sixth nerves that innervate the external and internal recti of the two eyes. There are many facts which tend to show that the first stage of convulsion is a transient paralysis due to a sudden discharge of inhibition centres. These are of a higher, more developed class than the centres for motor discharges, and would be affected first. We would have then loss of consciousness, inhibition of motion and muscular relaxation; then motor discharges and tonic and clonic convulsions.

3. The temperature on the paralyzed side was one degree higher than normal, and higher by a degree than that of the other side. This is the rule in intracerebral hemorrhage and hemiplegia, but the speaker was not aware that it has been established in cortical hemiplegias. In meningeal hemorrhages the temperature is often below normal according to Minot.

4. The presence of hemianæsthesia.

The patient died on the third day. Post-mortem showed chronic pachymeningitis over both convexities, but more on the left side. On the left convexity there was a very extensive fresh meningeal clot pressing upon and flattening especially the upper half of the central convolutions. Brain substance normal.

Dr. M. Allan Starr related the history of a case of

CORTICAL EPILEPSY WITH TEMPORARY APHASIA; SYPHILITIC GUMMA COMPRESSING THE LEFT SECOND FRONTAL CONVOLUTION IN ITS LOWER POSTERIOR PART; RECOVERY.

Chas. S., aged thirty-two, had always been healthy and a hard worker. He had an attack of sciatica four years ago, and three years ago had a hard chancre. He had never had convulsions or nervous affection. Family history good. During November, 1886, and the first two weeks of December he did not sleep well, was slightly dizzy, his head ached a good deal, chiefly at night. December 15, while walking with a pail in his right hand, he suddenly let it drop, losing all power in hand and arm. There was numbness in the hand. He was unable to speak to his companions. He did not feel dizzy or notice any pain in the head; he did not lose consciousness or fall. He understood his friends' questions but could not answer. Power in the hand and arm, and speech returned within half an hour. The next morning he went to work, as well as usual. Two days later a second attack occurred, beginning with a numb feeling in the tips of the fingers, gradually extending up the hand and arm. Then the fingers became rather forcibly flexed and stiff, but by a voluntary effort he could straighten them. No clonic spasms of fingers, and wrist and elbow were not bent. The numbness and stiff feeling soon extended to the face, which was drawn to the right side with some force. Speech was again lost. No loss of consciousness. The attack lasted about twenty minutes. Such attacks had occurred every other day, then every day, and finally twice a day up to January 3d, and during this time the headache and insomnia were increasing steadily. The character of the attacks was not uniform. Sometimes the spasm would begin in the face, though usually the arm was first affected. Both were involved in every attack, but the spasm and numbness never reached the leg. The hand felt cold during the attack, though warm to the touch. On one occasion he had for four days great difficulty in making himself understood by words. Examination by Dr. Starr showed slight paresis, and slight tactile anæsthesia in right hand; no affection of face or speech, no cardiac symptoms. Though suffering from headache, percussion of skull did not reveal any tender spots. Thrombosis, endarteritis syphilitica, diffuse encephalitis with sclerosis were excluded, and the diagnosis was reached of gumma in the membranes resting upon the brain surface, giving rise to irritation and consequently to an occasional nervous discharge, but not of sufficient size to cause any destruction. Location of tumor was equally clear: the relative situations of the cortical centres for the arm, face, and for the movements of speech in the lower two-thirds of the anterior central convolution, and in the posterior part of the third frontal convolution were likened to a reversed L. All these centres were irritated during the attacks, the irritation sometimes beginning in one, sometimes in another. If the tumor pressed upon the lowest posterior part of the second frontal convolution which would lie inside of the L, an irritation radiating from it might reach all three centres equally. The total intermission of the local symptoms might be explained by such a location, since no symptoms were known to occur from injury of this part; the fact that numbness in the hand and face uniformly accompanied the attacks of spasm seemed to indicate that the areas for these parts coincide with the motor areas.

Another point of interest was the distinctly motor character of the aphasia.

The treatment ordered was, first, inunction of mercury, and, second, iodide of potash daily in divided doses. He had one attack two days after beginning treatment, but since that time he had had no return of the symptoms. Iodide of potash was still being taken.

Dr. Seguin had seen several cases whose symptoms resembled those of the case recorded in Dr. Starr's paper. The prognosis of even non-syphilitic cortical lesions with this symptomatology is not absolutely unfavorable. One of the cases to which he referred was that of a Cuban who came to his clinic about nine years ago. He had never had syphilis, yet he described epileptic attacks of the true cortical kind, such as have been obtained by experiments upon animals during the last few years. The hand would become numb, and then the seat of a vibratory sensation; finally, contraction would occur in the hand, then the face, and almost simultaneously the leg would be affected, and he would lose consciousness. According to his friends' account general convulsions then occurred. He had had quite a number of these seizures; yet examination showed no anæsthesia, no affection of the optic nerve, and, so far as the speaker could recollect, no motor impairment. The patient had received a preparation composed mostly of the bromide of potassium to which a little of the iodide was added. He improved immedi-

ately, and four years ago the attacks ceased. Once in a while he has the sensation of wires in the hand, and the hand becomes stiff, but the face is never affected. The case was a beautiful illustration of the localization of a lesion in the centre of the hand, the discharge radiating to the face and leg of the same side, then to the opposite side, with loss of consciousness.

The patient had also been the object of the bracelet experiment. He was a powerful man, and had exerted great force, arresting many attacks in this way. The speaker was satisfied that syphilis was absent, while the amount of iodide was too small to explain a cure upon the ground of a syphilitic affection.

DR. STARR had been much interested in the case which Dr. Seguin had related. He had recently had a case of unilateral convulsions in his office. The patient was a small boy. The attack commenced in the eyes and face. The eyes turned to the right, then the head turned to the right, then the arm, then the leg, became affected. During the attack the speaker had asked suddenly, "What is your name?" The boy promptly replied, "Arthur," and then relapsed into the convulsion. He supposed that the reply was reflex, as the boy was unconscious at the time, and did not afterward remember the occurrence. He would like the opinion of the members upon the point.

DR. DANA asked what Dr. Seguin had considered the lesion in his case.

DR. SEGUIN had never ventured to surmise, beyond the fact that there was a nerve lesion, and that there was no syphilis in the case.

DR. STARR asked whether in localized convulsion numbness was not the rule.

DR. SEGUIN replied that it was; but he did not know that the reason was yet sufficiently established, although von Monakow had associated anæsthesia with lesions of the motor zone.

DR. SHAW referred to a case seen first four years ago. While at work as a jeweller the patient fell off his bench in a convulsion. The face and the left arm were convulsed; the leg was not affected; sometimes only the side of the face was affected. He had seen many of these attacks limited to the side of the face in his office. The patient complained of numbness in the arm and side of the face, and the speaker felt sure that the tactile sensibility was not as good upon that as upon the other side. The patient denied syphilis. Upon ophthalmic examination the nerves were found pale, and the visual field restricted in its upper part. There was no change until about six months ago, when, without loss of vision, he was found to have choked disk; this had gone on to atrophy, and the man was now blind. There was no paralysis. From the choked disk the speaker had now diagnosticated a tumor, but he referred to the case on account of the anæsthesia and the spasms, and their resemblance to those in Dr. Starr's case.

DR. SACHS referred to the case of a man who, some years ago, while working upon the capitol at Albany, had fallen some distance, and was found unconscious, but recovered. A few weeks later he developed symptoms which alarmed his friends, and he had now some of the physical and nearly all of the mental signs of cerebral paresis—the irregular pupils, the facial tremor, the tremor of the tongue, and the deteriorated mentality. The speaker referred to the case because of the traumatic incident, and because every three or four weeks this man had an attack of numbness beginning in the fingers and creeping up the right arm to the face. There never were convulsions, but both the patient and his wife, who is a very intelligent person, say that there is paralysis. After three or four hours both the paresis and the numbness disappear, and he has a very severe headache, lasting one or two days. The speaker thought there was a question of chronic meningitis with encephalitis possibly in this case. It was evidently a cortical affair.

DR. DANA thought that cortical epilepsy might develop like idiopathic epilepsy without an appreciable lesion. He recalled a case, that of a young man who was kicked in the front of the thigh by a horse. Twitching of the leg developed similar to that of cortical epilepsy. Thrilling and numbness of the arm and face followed. In a year true hemiepileptic attacks, during which he lost consciousness, developed, and upon giving him ether for stretching the nerve he went into the status epilepticus. There was no history of syphilis. Apparently cortical epilepsy was developed just as true idiopathic epilepsy in other cases.

DR. E. C. SEGUIN read a paper entitled,

A CONTRIBUTION TO THE PATHOLOGY OF THE CEREBELLUM.

A detailed account of one case was given, and specimens, gross and microscopic, illustrating its pathological anatomy, were shown. Three other cases of cerebellar disease were briefly presented, as card specimens with their anatomical demonstrations. The following is a summary of Case I.: male patient, forty-five years old at time of death; a retired officer of the U. S. Navy. Eighteen years before death illness began with headache, not strictly occipital, and one or more seizures of an epileptiform or apoplectiform character. These were followed by impaired vision and more or less continuous headache, fronto-occipital. Later appeared nystagmus and typical cerebellar titubation, slight slowness of speech. There was no distinct paralysis, true ataxia, anæsthesia, vertigo, or mental impairment. During several years, from 1877 to 1883 or 1884, the only symptoms were slight frontal headache, defective vision, partial atrophy of both optic nerves, nystagmus of varying form, slight slowness and indistinctness of speech, increased patellar reflex, and titubation.

In February, 1885, an epileptiform seizure left behind it partial left hemiplegia without contracture and anæsthesia. Death on 22d of April, 1885, preceded by a set of distinctly bulbar symptoms; increased dysarthria, dysphagia, salivation, pyluria, also increasing stupor.

Lesions.—Cyst of cerebellum destroying the caudo-ventral part of the middle lobe, not involving frontal third of the vermis superior, penetrating into the right lateral lobe as far as the nucleus dentatus, not destroying it, and probably exerting only slight pressure upon the floor of the fourth ventricle. There were also found: 1. A small hemorrhagic focus two millimetres in diameter, in the ventral half of the pons on the right side in the midst of the pyramidal fasciculi. This explained the left hemiplegia, and caused by it, could be traced a complete descending degeneration of the right pyramidal tract into its subdivisions in the spinal cord. 2. Very extensive arteritis obliterans of the encephalic

vessels, causing numerous, mostly symmetrical, foci of softening in the cerebral hemispheres. The only system degenerations which could be traced to the loss of substance in the cerebellum were a moderate reduction in the size of the opposite, left, olivary, and partial atrophy of the right restiform body.

The author called attention to several conclusions to be drawn from a study of these four cases. 1. As to diagnosis. Tumors of the cerebellum produce very variable symptoms; but one symptom, viz., cerebellar titubation, is, as claimed by Nothnagel in 1876 or 1877, pathognomonic of a destructive lesion of the middle lobe of the cerebellum, more especially its caudo-ventral masses. In Dr. Seguin's cases optic neuritis or atrophy had not failed, which was in marked contrast to his experience with tumors of the cerebral hemispheres, which do not usually cause lesion of the optic nerves (1 : 5 or 1 : 7). Vomiting was a frequent symptom; occipital headache, and rigidity of the muscles of the back of the neck were less frequent but very valuable symptoms.

2. As to therapeutics. Three of the patients had obtained repeated relief from serious symptoms, paroxysms of headache, vomiting, and epileptiform attacks, by the use of the iodide of potassium, in doses of from thirty to sixty grains, three times a day.

3. As to prognosis. Two of the patients did not die of their cerebellar diseases (both cysts), but of complications: Case I., of diffused arthritis obliterans and consequent softening in various parts of the brain (including impaired nutrition of the bulbar nuclei); the other case, II., of an acute tubercular meningitis. Consequently we may hope, in a few cases, to cause or to witness an arrest of the cerebellar disease. The disorder in voluntary movements, and the already developed lesions of the optic nerves, are, of course, irremediable.

Dr. Bradner spoke by invitation. He had been the attendant in the case of a child to which Dr. Seguin had referred. He had done lavage of the stomach a number of times during three weeks, but had then refused, believing that the child had brain disease of some form. He saw the patient first in November. The vomiting was always in the morning; there was no pain connected with it then, although a frontal headache had developed during the last few months. The treatment prescribed by Dr. Seguin had been the iodide of potash, fifteen grains, t. i. d., increasing five grains daily until 100 grains were taken at a dose. The course had been interrupted by several attacks of acute gastritis, but the child had had those attacks previously; they did not appear to depend upon the medication. The eyesight had been perfect; the child could detect the smallest point made by a lead pencil or needle. While using the iodide his headache had improved, as had other symptoms; but he retained his old man's gait.

Dr. Seguin remarked that, though seeing well, the child had typical choked disk.

Dr. Bradner added that, since seeing Dr. Seguin, he had obtained a history of injury in the case. Two years ago, and just before the commencement of his illness, he had, while trying to skate, fallen, and received a severe blow on the back of his head. One result of this injury had been abiding terror at the sight of a body of water or ice.

Dr. Shaw had shown a child at the American Neurological Association of 1878, on account of a peculiar ataxic gait, like that of locomotor ataxia. The later symptoms had pointed to a tumor of the cerebellum.

Dr. Putnam Jacobi referred to the recent collection of cases by Bernhardt. All cases published previous to 1884 had been collected by Nothnagel. Dr. Seguin's cases tended to confirm Nothnagel's laws. There are many resemblances between the symptoms of cerebellar tumor and those of tumor in other parts of the brain. The peculiar violence of the headache and the choked disk found in most cases of cerebellar disease might, he thought, be due to the increased pressure of a tumor confined to the tentorium. This element had not been commented upon, and he would like Dr. Seguin's opinion upon it.

Another point referred to the fact that the laws formulated by Nothnagel recognize the possibility of complete latency of the tumor, no symptoms at all being present when but one lobe of the cerebellum is affected, such symptoms appearing only when the tumor encroached upon the central lobe. In one of Dr. Seguin's cases the tumor occupied only the lateral lobe. Of course, an indirect affection of the central lobe might be present even in such a case.

Dr. Lezinsky referred to a case to which he was called in consultation by Dr. Alexander. The boy had the typical gait of spastic paraplegia; any attempt to stand caused spastic contractures in the limbs. The ankle clonus was present, and the knee-jerk was exaggerated. There were no cerebral symptoms; the fundus was normal in both eyes. The father and mother were both alcoholic and unworthy people. Finally the child became unable to walk, but there were still no cerebral signs, no vomiting. Two months before death the fundus was still normal. Later tremor developed, and paralysis of the abducens, of the fifth, and of the third nerves. Total blindness occurred. The nurse was positive that the child could see nothing. It died in a convulsion. Unfortunately the body was immediately frozen, and the specimen was unfit for sections. The tumor was found occupying one side of the cerebellum. The spinal cord was not fit for examination. There was a well-developed meningitis, and the paralysis was accounted for by considerable exudation about the cerebral nerves. One peculiarity had been a subnormal temperature during one stage of the case.

Dr. Starr had had occasion, some time ago, to make a collection of cortical lesions from American literature. He had at the same time made a collection of cases of cerebellar disease from the same sources. As the data obtained corroborated Nothnagel's results, he never published them; but Dr. Seguin having remarked upon the value of corroborative evidence, he would briefly refer to them now. From 1860 to 1861, 160 cases of cerebellar disease were reported in American literature. In only 40 of these were the symptoms and the autopsies described with sufficient accuracy to warrant conclusions. These 40 the speaker had quite thoroughly analyzed. In 4 there were no symptoms; in one of these there was congenital atrophy of the cerebellum; in 2, abscesses, and in 1 a large cyst. Of the remaining 36 presenting symptoms there was headache in 36; incoordination in 25; vertigo in 20; vomiting in 18; blindness in 14; dim vision in 6; diplopia or strabismus in

7; deafness in 7; facial spasm or paresis in 4; hemiplegia in 9; general paralysis in 4; mental symptoms in 8; stupid, 7; mania, 1; convulsions in 7; sexual desire increased in 2. Males, 23; females, 17. Ages, between 1 and 20 years, 11 cases; between 20 and 40 years, 16 cases; between 40 and 60 years, 9 cases; over 60 years, 1 case: age not stated in 3.

In 2 of the 11 cases in which incoördination did not occur, the lesion probably involved the middle lobe. In cases where incoördination occurred, various parts of the cerebellum were involved, but the probability was that the middle lobe was affected in the majority. There were only two instances of increased sexual desire. Bernhardt had found but one instance in 90 cases of cerebellar tumor, and Nothnagel but 2 cases. The speaker thought that it might be thrown out as a symptom of cerebellar disease, and regarded as one of accidental occurrence. The escape from vertigo in Dr. Seguin's case, was explained, perhaps, by the recent discoveries in the anatomy of the course of the acoustic nerve. This nerve served for the sense of hearing and the sense of space. The centre for hearing is in the pons. Edinger finds the centre for equilibrium in the cerebellum to which acoustic fibres pass by way of the middle peduncle. From this centre the central tract probably passes onward to the superior peduncle. Dr. Seguin says that the superior peduncle escaped in his case. It is, therefore, natural that vertigo should not have occurred.

The tendency to rotation was an interesting feature in these cases. There was a tendency to fall or turn forward, in two cases the lesion was a tumor in the vermis in the anterior part. There was a tendency to fall to the right in two cases, in one there being a tumor in the left middle peduncle, and in the other an abscess in the same part. There was a tendency to fall to the left in two cases, in one there being an abscess in the right middle peduncle, and in the other a tumor in the left middle peduncle. A patient of Nothnagel, whom the speaker had seen in Vienna, when sitting up in bed had always a tendency to turn to the right side. Nothnagel considered this due to vertigo. It was only present when the patient was erect. The patient felt as though about to fall to the left side, and hence turned to the right. This case had a tubercle of the left middle peduncle of the cerebellum. Nothnagel considered this symptom only produced by affection of the middle peduncle. In the two cases in the table where the tendency was to turn to the right there was disease of the left middle peduncle; while in the two in which the tendency was to the left, in one the right peduncle, and in the other the left peduncle was affected. No rule can, therefore, as yet be laid down as to the cause of this symptom.

Dr. English had had charge of the case which formed the subject of Dr. Seguin's paper, and he congratulated the Society upon the progress which had been recently made in the diagnosis and treatment of cerebellar disease. Early in 1878, Dr. Seguin had written him a letter accurately diagnosticating this case as seen in autopsy.

Dr. Seguin closed the discussion. He was not surprised to learn of the little boy's fall, as he was a firm believer in the traumatic origin of these conditions. It was very difficult to obtain a history of fall. He could not give an opinion upon the question propounded by Dr. Putnam Jacobi. In regard to ascribing the vertigo to the acoustic nerve, he was not yet certain that the acoustic nerve had cerebellar origin. He thought it would be difficult to trace fibres through the lateral peduncle of the cerebellum, the vermis, and the anterior peduncle. He said Dr. Starr had probably made a mistake when he referred to Nothnagel connecting rotation with disease of the middle peduncle. Middle vermis he had probably meant to say.

Dr. Starr accepted the correction.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 9, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. George W. Vogler, reported a case of

SUPPURATIVE INFLAMMATION OF THE LIVER IN A CHILD; OPERATION AND RECOVERY.

M. C. S., aged twelve, on October 7th first complained of intermittent pain over the right hypochondriac region, and at the same time she began to favor the part by slightly bending forward and to the right side when standing or walking. A week later the pain became more severe, and interfered with sleep; walking was discontinued owing to pain; and some fever manifested itself, with marked impairment of appetite, coated tongue, thirst, cloudy urine, and constipation.

November 12th, five weeks after the commencement of her illness, I assumed charge of the case. I found her in bed, greatly reduced in flesh, with an anxious expression, and suffering intensely. Her favorite position was a sort of sitting posture, with the body bent forward and to the right, and with the lower limbs flexed strongly upon the abdomen. There were irregular attacks of chilliness or rigors; temperature was elevated every night; no cough, jaundice, or vomiting; there was, however, sallowness of the skin, and dark, turbid, and scanty urine. Examination revealed a dark bluish swelling some three inches in diameter in the right hypochondriac region, bordered by the sixth rib above, the tenth below; and laterally by the linea mammillaris and the linea axillaris. The swelling was about three-quarters to one inch in height, and presented all the appearances to sight and touch of a carbuncular development. It was hard, firm, and quite painful to the touch. There was no fluctuation. She was put upon concentrated nourishment, stimulants, and, medicinally, on syr. ferri iodidi, and opiates and quinine. Locally an ointment was applied every eight hours, composed of camphor, opium, ext. belladonnæ, comp. resin ointment, and cosmoline.

This plan of treatment was continued for five or six days, with the effect of markedly softening the swelling and causing it gradually to diminish in size, and the development of a central point of concentration just over the eighth intercostal space. I thought I detected fluctuation on palpation, but obtained nothing but blood on aspiration with the exploring needle. Anodyne flaxseed poultices were now used, and on the 21st instant I prepared to operate, all the conditions seemingly pointing to the retention of deep-seated pus. I decided to treat the case by free incision, the thorough evacuation

of the pus (if any), and the prevention of reaccumulation by complete drainage by means of rubber tubing.

The little patient was thoroughly etherized, and, after selecting a favorable point by aid of the exploring needle, a free opening was made, one inch or more in length, down through the eighth intercostal space, about one and a half inches to the right of the linea mammillaris. Immediately upward of eight fluidounces of pus flowed from the wound. At first it was "laudable," free from odor, but streaked or marked with biliary coloring matter; toward the end it assumed the very dark condition usually spoken of as "chocolate-colored pus," due to the presence of blood or disintegrated hepatic tissue. Gradual pressure over the hepatic area aided in its rapid and free evacuation, the bulging over the intercostal spaces disappeared, and for the first time the outlines of the ribs were readily recognized. A probe was now passed through the wound under the ninth rib, and it entered in an obliquely downward direction, to the extent of four inches, toward the linea alba, and three inches obliquely upward toward the sternum, in depth perpendicularly about two and a half inches.

A perforated rubber drainage tube doubled upon itself, was introduced into the depth of the cavity, enabling free drainage, and the daily injection of carbolized oil (two to sixteen fluidounces) through one end, and its escape through the other. Warm cataplasms were continued night and day. After some five days the tube was replaced by one of a smaller calibre, and entirely done away with the ninth day after the operation. A small piece of lint dipped in carbolized oil was used a few days longer, simply to keep the cut from closing, and insure thorough healing from within outward. Finally, carbolized zinc ointment completely healed the wound by December 8th. Her improvement and rapid convalescence after the operation were wonderful. Internally she has been taking cod-liver oil emulsion with hypophosphites and syrup. ferri iodidi.

December 12th, she was walking and playing about her room, and on January 15, 1887, she was fully recovered.

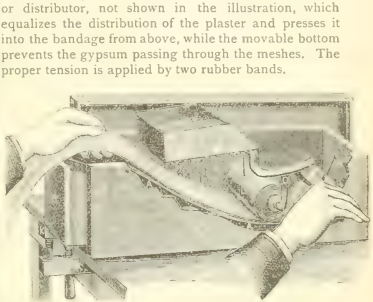
Of the very interesting features of this case, the first is the *age* of the patient, viz., twelve years. The statistics show this serious ailment to be rare in children, being seldom seen under the age of twenty. In seeking for the *cause* of the disease in this case, I am led to adopt one of a traumatic nature, notwithstanding that most authorities show but a very small percentage of cases due to external violence. My patient revealed no previous malarial, dysenteric, metastatic history, or any other inflammatory and ulcerative process in the gastro-intestinal canal, which are generally looked upon as the chief disturbing influences or causes of suppurative inflammation of the liver. Careful inquiry elicited the following history and probable cause: About four days previous to the commencement of her symptoms, she carried flower plants from the yard up to the fourth floor of the house. One of these plants was, owing to its weight, entirely beyond her strength, yet, after four efforts, she succeeded in landing it on the fourth floor. She described the pain felt by the pressure, and the weight sustained over the right hypochondriac region in her struggles to complete her task. The child is of a very light build and delicate, and it is quite probable that this external violence originated her painful affections.

This case happily illustrates the good results of free incision, perfect drainage, and the rapid healing under carbolized oil.

DR. H. AUGUSTUS WILSON read a paper on

A NEW APPARATUS FOR PREPARING DRY GYPSUM BANDAGES.

It consists of an ordinary box-bandage roller, with the addition of the following: A movable bottom, A, A, A, held in contact with the outermost layer of the bandage, as it is rolled, by a rubber band B, and at the other end by a hinge-joint C. Upon this movable bottom, and just in front of the crank, is a flood-gate or distributor, not shown in the illustration, which equalizes the distribution of the plaster and presses it into the bandage from above, while the movable bottom prevents the gypsum passing through the meshes. The proper tension is applied by two rubber bands.



A hopper, E, is provided with an arm, F, bent in such a manner as to be raised by the crank at each half turn, and upon being released it falls, throwing down a quantity of the powder upon the bandage in front of the distributor. A compartment, H, H, H, occupying the otherwise waste space under the movable bottom, is utilized as a receptacle in which may be kept the gypsum when the apparatus is not in use. A scoop accompanies the apparatus with which to take gypsum from the compartment and fill the hopper. The entire affair can be securely held to a table by a clamp, K. Elastic bands are used for springs, because they are inexpensive and can be very readily replaced when worn out.

The method of using is, first to pass the end of the bandage to be rolled over the movable bottom, under the distributor, and attach to the crank. The hopper is now to be placed in position and, by means of the scoop, filled with a sufficient quantity of gypsum. While the crank is turned with the right hand the left guides the bandage, which may be watched, over the hopper as it is being rolled.

The bent arm of the hopper is so arranged that the fall of the hopper may be sudden or gradual, and upon this depends the quantity of powder discharged. When the crank is turned very slowly the hopper is raised slowly and descends with the motion of the crank, and scarcely any gypsum is precipitated, and, of course, the converse follows. This being clearly understood, a very slight experience will enable any one to control the action of the hopper with the crank.

When a bandage is finished, the crank is withdrawn

sufficiently to disengage it from the bent arm of the hopper, and while the left hand holds the bandage a quick reverse turn of the crank enables it to be easily withdrawn. The gypsum remaining on the movable bottom is now discharged into the compartment by placing the hopper to one side, detaching the spring, B, and raising that end.

The apparatus is applicable to the rolling of the ordinary surgical bandage by detaching the rubber spring, B, thus allowing the movable bottom to drop out of the way. It prepares the dry gypsum bandages evenly and quickly. It is very simple in its construction and action. It cannot get out of order, except by the breaking of the rubber bands. It is inexpensive.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 17, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

ADDRESS BY THE PRESIDENT.

THE PRESIDENT delivered an address which was largely devoted to the reprehensible means employed by certain members of the profession for advertising themselves in the community.

DR. C. L. DANA read a paper on

SPASTIC ATAXIA, FUNCTIONAL AND ORGANIC, AND THE COMBINED SCLEROSIS OF THE SPINAL CORD.

The object of the paper, he said, was to show a class of cases, not very rare, which correspond to some extent with ordinary progressive locomotor ataxia, but to a much more marked degree with spastic paraplegia. This affection it is important to recognize both for prognosis and treatment.

He had been able to collect forty-five cases of combined sclerosis, observed by various authorities, including two, the history of which, with the autopsies, were reported for the first time in the present paper, but all except sixteen of these he felt obliged to exclude on account of various circumstances which he thought prevented them coming properly under the head of the class of cases of which he was treating, those so admirably described by Gowers, and designated by him as ataxic paraplegia. Dr. Dana had notes of seven cases, six of which were in males, and one in a female; and he described several of them in detail.

In referring to the symptoms, he said that there was gradually increasing weakness of the limbs, with some loss of power of coördination; but the lancinating pains of tabes were, as a rule, absent, while the knee-jerk was increased, instead of being lost, as in the latter. The "Argyll-Robertson" pupil was also seldom seen. As the disease advanced, the muscular power became more and more impaired; while the incoördination did not proportionally increase, but was overshadowed by the increasing paralysis.

The increased myotatic irritability continued, and stiffness and rigidity developed as its consequence. "Thus," as Dr. Gowers so well described it, "the aspect of the patient comes to be that of spastic paraplegia; the feet drag as the patient walks, shake from clonus when he stops, and the legs are hauled forward with visible effort at each step." Sexual power is often lost early in the disease. The sphincters are frequently impaired, but the impairment rarely reaches a considerable degree. There is, as a rule, no wasting of the muscles, and no change in their electrical excitability.

The pathological condition found on post-mortem by Dr. Dana was chronic cervico-dorsal myelitis affecting the lateral columns primarily, the gray matter secondarily. In a case, the drawings from which he presented, there were secondary degenerations in the lateral columns, and ascending and descending development of sclerosis in the columns of Goll. In addition, there was sclerosis of the crossed pyramidal tracts, most marked in the dorsal region, and sclerosis of the cerebellar tracts to a moderate extent. The sclerosis in the columns of Goll was most marked in the cervical region. According to Gowers, in all cases the spinal cord has presented sclerosis of both posterior and lateral columns; but the precise extent and degree of the degeneration seem subject to considerable variations. As a general rule, the sclerosis of the posterior columns differs from that of tabes in two particulars. First, it is not more intense, and is often less intense, in the lumbar than in the dorsal region of the cord. Sometimes, indeed, in the middle and lower parts of the lumbar region the posterior columns may be free from sclerosis, although it is considerable in the dorsal region, and at the junction of this with the lumbar enlargement. The second difference is that the sclerosis has rarely the special intensity in the root-zone of the postero-external column that characterizes the lesion of tabes.

The prognosis as to life, Dr. Dana went on to say, is better than in simple tabes dorsalis. The disease has little tendency to cause death; indeed, according to Gowers, the fatal cases have, for the most part, been atypical, and did not convey an accurate idea of the character of the disease. The chief danger to life is from the accidents common to all chronic spinal affections, and especially from kidney disease secondary to retention. So far as the prospect of recovery is concerned, the prognosis is unfavorable, and one case is on record in which the affection had already lasted thirty years.

The treatment does not vary greatly from that of locomotor ataxia. Rest is a very important element and electricity, both static and in the form of the faradic current, is useful. Orthopædic appliances to support the enfeebled limbs are often of great service. Anti-syphilitic treatment should always be thoroughly tried, and later large doses of iodide of potassium are to be resorted to. In conclusion, Dr. Dana said that while no name has as yet been found which properly described the disease clinically, he thought the designation combined fascicular sclerosis is applicable from a pathological point of view. (Dr. Dana exhibited a number of microscopical specimens and photographs illustrating the subject.)

DR. M. A. STARR said that he thought that we still had to look for a thoroughly satisfactory name, and that the one proposed by Dr. Dana—combined fascicular sclerosis—ought not be accepted, since the pathological changes found after death show that the affection is not entirely fascicular in character. The diagnosis between tabes and combined sclerosis, he remarked, is often very difficult; and, again the occurrence of general paresis in connection with tabes sometimes makes us hesitate in arriving at a diagnosis.

Dr. G. W. Jacoby expressed the opinion that our knowledge of this affection would not be much increased by the study of purely clinical pictures.

Dr. E. C. Seguin related a case of his own, and presented sections of the cord of his patient; stating that they seemed to show that there were instances in which the pathological changes present were intermediate between fascicular sclerosis and disseminated sclerosis.

Dr. W. R. Birdsall referred to the prevalent opinion as to the irregularity of this class of scleroses, and spoke of Gowers's attempt to separate cases of ataxic paraplegia, as distinct from spastic paraplegia. This classification, he thought, was justified from a clinical point of view, and the affection could not properly be designated as a fascicular sclerosis.

The President suggested that perhaps the sclerosis followed the course of the minute bloodvessels whose extensive network served to connect and bind together the various fasciculi of the spinal cord. This anatomical fact would, he thought, satisfactorily explain these mixed forms of sclerosis. He thought the subject of the paper one of great practical importance to all physicians on account of the frequency with which spinal disease is now met with.

The discussion was brought to a close by Dr. Dana.

AMENDMENT TO THE BY-LAWS.

On motion, it was voted to strike out Section 3 of Article 18 of the By-laws; this amendment doing away with the privilege afforded by the section referred to of compounding for annual dues.

NEWS ITEMS.

An Act to Regulate Promotion in the Medical Department of the Army.—The following are the reasons given in the report of the Committee on Military Affairs to Congress, for the adoption of the bill to establish the order of promotion in the Medical Department of the Army.

The assistant surgeons of the Army who were appointed under the act approved July 28, 1866, reorganizing the Army, after the war, have been subjected to several changes in their relative positions on account of variations in the interpretation of the laws under which they were appointed. The statutes in force at the time were the act of July 28, 1866, and the Army Regulations enacted thereby; the act of March 2, 1867; and the old sixty-first article of war. The contemporary construction of all these was that an assistant surgeon ranked in the Medical Corps, first, according to the date of his commission as assistant surgeon, without regard to his military rank as captain or lieutenant; and, second, that his position among those having the same date of commission was fixed by executive act, the factors of prior service and proficiency in the examination required on entering the corps being presumably taken into account by the President.

The second construction of these acts, made in 1878–'79, was to the effect that precedence was fixed exclusively by date of rank as captain or lieutenant, irrespective of date of commission as assistant surgeon. The third construction was made after the passage of the act of July 3, 1884, and under it assistant surgeons ranked (1) according to date of commissions as assistant surgeons, and (2) among those of the same date seniority was given to the one who had had longest prior service as a commissioned officer, whether of the line or of the Medical Department. Consequently, from 1866 until 1879 one order of precedence obtained, from 1879 until 1884 another, and from 1884 until now still another, and under each order promotions to the grade of surgeons have been made which could not have occurred under either of the others.

As the promotion of an officer depends upon his position in relation to other officers, it will be readily seen that these different orders have given rise to controversies, each party claiming that the interpretation of law which gave him precedence was correct. These controversies have now lasted so long, have given rise to so extensive a correspondence, and involved interests of so much importance, that without expressing any opinion as to who has the soundest claim to precedence, it is deemed best to establish another order of promotion, which, while not destroying any legal or equitable rights, shall be precise and definite, and shall have the effect of quieting controversy and putting a stop to dissension, which may eventually cause much ill feeling in the Medical Corps. This the bill under consideration does. It applies only to the assistant surgeons appointed under the act which has received conflicting interpretations. It fixes the same standard for precedence that is now established for pay—*i. e.*, length of service, and it makes twenty years' service the time entitling an assistant surgeon to promotion. It provides that service under present commission shall count from a certain date, that of the commission itself, instead of from the date of acceptance, to prevent the disarrangement of those who having had no previous service, and being of the same date, accepted on different days. It compensates for loss of relative status by security of tenure, and by establishing a fixed time for promotion. It requires a successful examination antecedent to promotion, as is now the law, and it forbids an increase of the whole number of officers in the medical department.

Under the present law all the assistant surgeons concerned would probably receive promotion in between four and five years. Should this bill become a law the time will be shortened a year or eighteen months. It causes no permanent increase in the number of surgeons. After the promotions under the proposed law have taken place, no further promotions to the grade of surgeon can be made until the number is reduced below that now allowed by law, nor will the promotion of an assistant surgeon under it leave a vacancy to be filled by a new appointment, nor does the proposed act retard the promotion of assistant surgeons appointed under other than the act of July 28, 1866.

The list herewith shows the order which the bill proposes to establish in place of the controverted ones:

1, Curtis E. Munn; 2, Henry M. Cronkhite; 3, Robert M. O'Reilly; 4, Julius H. Patzki; 5, Joseph K. Corson; 6, Calvin De Witt; 7, Benjamin F. Pope; 8, John H. Bartholf; 9, John M. Dickson; 10, J. P. Kimball; 11, Ezra Woodruff; 12, Clarence Ewen; 13, Charles L. Heizmann; 14, Robert H. White; 15, Alfred C. Girard; 16, Joseph B. Girard; 17, John V. Lauderdale; 18, Leonard T. Loring; 19, Daniel Weisel; 20, Frederick W. Elbrey; 21, Washington Matthews; 22, John D. Hall; 23, Philip F. Harvey; 24, Stevens G. Cowdrey; 25, Charles P. Byrne.

A CONGRESS ON CREMATION.—An international congress of societies and private persons interested in cremation will be held at Milan in the month of September, 1887. The programme of the Congress will include (1) a general statement of the progress of cremation among different nations; (2) a proposal for constituting an International League of Cremation Societies; (3) a proposal for international legislation, regulating the removal of bodies from one country to another, and the methods of cremation and conservation of the ashes, from the point of view of public hygiene and of legal medicine; and (4) other subjects of direct collateral interest connected with cremation. An exhibition will at the same time be held of plans, models, and designs, books and literature relating to crematories, and all other matters connected with cremation. Among the Honorary Presidents of the Congress are MM. Cantoni (Pavia), Crocq (Brussels), Koechlin-Schwartz (Paris), Moleschott (Rome), Sir Henry Thompson (London). Dr. Malachie, of Milan, is the President, and Dr. Poni Caëtan the Secretary, to whom all communications should be addressed. The preliminary list of members of the Congress is already extensive.—*British Medical Journal*, Feb. 12, 1887.

[illegible] or medical corporation for the promotion of the study of the medical sciences, from both a practical and a theoretical point of view, as well as for the promotion and protection of professional interests, has been established at Lerida, in Spain. It is entitled El Colegio Médico Quirurgico de Lérida.

At a recent open competition for two colonial surgeoncies in the Philippines held in Madrid, more than thirty practitioners presented themselves as candidates, several of them evincing, as the Spanish medical press states, proofs of exceptional merit.

A LECTURE THERMOMETER.—F. C. Müller (*Berichte*, xix. 2175) recommends a large thermometer filled with sulphuric acid, blackened by a little sugar; sulphuric acid expands regularly, and as its coefficient of expansion is three and one-half times as great as that of mercury slight variations of temperature during experiments may be seen by a large class. Successive spaces of ten degrees of the scale, which is placed back of the thermometer, are differently colored, so that the audience can readily read the level of the acid.

RABIES TREATED BY CANTHARIDES.—A Russian medical journal relates cases of the bites of rabid animals successfully treated by cantharides, the Spanish fly, familiar to those who have been blistered in the old-fashioned way.

A wolf attacked three men, inflicting on one a large and deep wound in the left groin, tearing off a piece of skin several square inches in area.

The other men were wounded in the face, legs, and arms. It is well known to the profession that the bites of mad wolves are more dangerous than those of mad dogs, which is partly accounted for by the greater ferocity of the wolf, even when not rabid, and the more extensive wounds thereby resulting.

Cantharides plasters were applied to all the wounds, and powdered cantharides was given internally in three-grain doses, daily, to each of the three patients.

The internal administration was continued for a week, until the patients complained of some urethral heat and irritation.

Seven months have passed, and all the patients remain perfectly healthy.

The author, however, is familiar with the fact, that a large proportion of persons bitten by rabid animals escape hydrophobia, even when no treatment is adopted. He is, therefore, careful not to claim in this treatment a specific, and accordingly awaits developments.

OBITUARY RECORD.—ALBION D. WEEKS, M.D., of Providence, Rhode Island, died on the 10th inst. His health had been impaired for several months, but he had continued to practise until about four weeks previous to his death, which was caused by malignant disease of the brain. Dr. Weeks was born in Portland, Maine, in 1847. He was graduated at the University of Pennsylvania, and had established a very extensive practice in Providence. He was a Fellow of the Rhode Island Medical Society and Surgeon of the United Train of Artillery, one of the oldest military organizations in Rhode Island.

NOTES AND QUERIES.

[illegible]

To the Editor of THE MEDICAL NEWS,

Sir, [illegible] THE MEDICAL NEWS for Dec. 11, 1886, and Jan. 8, 1887, by Drs. Porcher and Guitéras, upon the influence [illegible] upon health, raise the question as to the existence of peculiar electrical or magnetic phenomena at the time. The suspended bar magnet in this [illegible] A [illegible] when placed [illegible] [illegible] when [illegible] [illegible] of [illegible] way, hence it is only by means of observations that are sufficiently comprehensive and precise that the questions that arise in connection with this subject can be settled. Yours truly,

M. A. VEEDER.

THE DEATH-RATE OF LYING-IN HOSPITALS IN THE UNITED STATES.[1]

BY BARTON COOKE HIRST, M.D.,

OBSTETRICIAN TO THE MATERNITY HOSPITAL OF PHILADELPHIA, AND OBSTETRICAL REGISTRAR TO THE PHILADELPHIA HOSPITAL

STATISTICS showing the death-rate in general hospitals, while interesting and instructive in themselves, are of little value for purposes of comparison, for the class of cases treated in one institution can differ so much from that in another as to make any comparison between the two impossible. This is true to a much less degree of hospitals devoted to the reception of women about to be confined; here the conditions are constant, the affection to be treated is always the same.

The collection and comparative analysis of the statistics of such institutions has been brought to a condition of great perfection in Europe, especially in Germany, with the result of exciting a spirit of emulation among the authorities of the obstetrical hospitals as to which one of them shall possess the best record, and the wide publication of these reports has had, moreover, the very valuable effect of making it impossible that a hospital should have a conspicuously bad record without giving some explanation for it. Such a collection of statistics in regard to the lying-in hospitals of this country does not exist; to supply this deficiency, therefore, the writer has devoted considerable time and attention, with the result of obtaining the records of 19,902 confinements during the six years, 1880–1885, divided among 34 hospitals.

Of the importance of possessing such knowledge it is almost unnecessary to speak. By placing the statistics in a tabulated form, the records of those hospitals which are unusually good may be compared with those that are conspicuously bad, and if the divergence in results between them is great some explanation for this fact must be sought. Then, again, the total result, the average mortality, may be compared with the average hospital mortality in other countries, and, most important of all, it will be necessary to contrast the mortality of obstetrics in hospital practice with that of general practice, as on the result of this comparison should depend the very existence of these institutions; for it must be conceded that no hospital, whether supported by the community or by private charity, has the right to subject its inmates to a danger of death much greater than if they had remained in their own homes, no matter how squalid they might be.

[1] Read before the Philadelphia Obstetrical Society, March 3, 1887.

The study of the following statistical table, therefore, will be divided under three heads: First, a study of the table itself, with a comparison of the individual records, and an explanation, if possible, of their wide divergence; second, a comparison of the average hospital mortality in this country with that of some other countries; and, third, a study of the relation that hospital mortality bears to the mortality of general practice.

Institution.	Total confinements, 1880–85.	Percentage of deaths.	Percentage of deaths from sepsis.
Baltimore, Maternity	1884	2.27	0.80
Boston, Lying-in Hospital	1800	0.61	3.10

St. Louis, Lying-in Hospital	923	1.42	1.28
Washington, Columbia Hospital	797	1.25	0.50
Total number of women delivered		19,902	
" " " died		8[illegible]	

It cannot be claimed that the preceding list is a complete one of all the lying-in hospitals in this country; there were some that ignored repeated requests for their statistics, there were others that refused to give them, and still others whose records when obtained were found valueless for the purposes of this paper. In addition to these hospitals una-

[1] 1882–85.

[2] 1882–85.

[3] Records prior to 1881 unreliable.

[4] Causes of death not given.

[5] Only reckoned for last three years.

voidably omitted from the list there may be others of whose existence the writer is unfortunately ignorant. It is improbable, however, that the addition of any records that have been omitted would seriously affect the final result. The number of cases dealt with is so large as to insure the approximate accuracy of the conclusions arrived at.

A death-rate of 2.59 per cent. of the women confined. It must be surprising to one who has not devoted much attention to the subject to find that, of the women of this country who perform the perfectly physiological function of childbearing in hospitals designed for their reception at such a time, 1 out of every 38 must die. One looks involuntarily to the table to learn if this represents the true state of affairs in all lying-in hospitals. If they all have a death-rate closely approximating this, then the only conclusion possible is that such a mortality is inseparable from childbirth in hospitals. A mere glance, however, suffices to show that the onus of producing a mortality as high as 2.59 per cent. of the women confined, rests not upon all, but conspicuously upon a few. Ten hospitals may be selected whose average mortality is 4.48 per cent. of the women confined; or, of every 22 women who are compelled to seek shelter in these institutions, 1 will die. On the other hand, ten hospitals may be selected, of which the average mortality is only 0.87 per cent., in which 115 women must be delivered before 1 dies. Can there be a satisfactory explanation for a divergence in results so wide as this?

It has often been asserted that unmarried primiparæ form the most unfavorable class of cases possible; that, in addition to the primiparity which is acknowledged everywhere as an unfavorable factor in obstetrics, the shame connected with the illegitimate birth exerts an almost murderous influence in raising the mortality among these women.[1]

It might, therefore, be expected that only hospitals devoted to this class of cases would be found among those contributing to raise the general mortality, while in those where the mortality was so low there would be found a large proportion of multiparæ. Again, a reference to the table of statistics will show the truth or the fallacy of this surmise. We shall find that the record of the Maternity Hospital of Philadelphia, an institution devoted entirely to the care of unmarried primiparæ, will show a death-rate of 1.39 per cent., while the Boston Lying-in Hospital, in which more than half the patients are married women and presumably multiparæ, although the annual reports give no information on this point, has a mortality of 3.81 per cent.

It may also be claimed that a high mortality is inseparable from a lying-in hospital that deals with a large number of women yearly; but if this is the case, it must be due to over-crowding, which can occur just as well in a small as in a large hospital, but is unjustifiable in either. And, in fact, if we look again to the table, we shall find the highest mortality in a hospital which reports only 60 cases for the six years. It is useless to look further for a satisfactory explanation for the high death-rate that prevails in many of our lying-in hospitals, for no good reason can be found, and the conviction is forced upon us that such excessive mortality is utterly unjustifiable. That this is true and that, even in institutions whose previous record had been simply shocking, an earnest effort toward improvement will accomplish much, is shown by the following table of the death-rate by years in two large hospitals.

DEATH-RATE PER CENT. OF WOMEN CONFINED.

Institute	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Boston, Lying-in Hospital	[illegible]	[illegible]	6.00	[illegible]	[illegible]	3.81
Philadelphia Lying-in Almshouse	[illegible]	4.08	3.42	7.31	3.17	1.52

The sudden decrease in the mortality of the Boston Lying-in Hospital, in 1884, was the result of a letter calling the attention of the managers to the really murderous death-rate of former years in that institution. The improvement begun in 1885 in the Philadelphia Almshouse still continues, the death-rate for the past year having been only 0.87 per cent. It is also gratifying to note the gradual improvement for the whole country shown in the following table:

Years	Women confined	Women died.	Death-rate per ct.
1880	[illegible]	85	3.03
1881	3320	98	2.54
1882	3272	90	2.74
1883	3207	121	3.77
1884	3595	67	1.50
1885	3704	75	2.02

This improvement is not steady, but, as may be seen, the death-rate for the last two years is lower than for any two years previous.

To conclude the study and analysis of the table of statistics, it would be well to fix a maximum mortality for lying-in hospitals, beyond which none should go without giving a satisfactory explanation. We have seen that there are 10 hospitals on the list with an average mortality of only 0.87 per cent., and among these hospitals are some which deal with the worst class of cases imaginable. It would seem, therefore, reasonable and liberal to fix this limit at 1.5 per cent. of the women confined, and I am happy to say that in future the State Board of Charities in Pennsylvania will probably demand annual reports from the lying-in hospitals throughout the State, in order that if any one of them shows an excessive death-rate, that fact may be pointed out to the managers of the hospital with a request for an effort to secure better results.

Now we may pass to the second division of the subject and compare the records of lying-in hospitals in this country with those of some hospitals in the most highly civilized states of Europe.

It would be impossible, were it necessary or desir-

able, to present a complete list of the lying-in hospitals, with their statistics, of the foremost countries of Europe. The brief little table that follows, however, will supply us with sufficient material to enable us to contrast the mortality of child-birth in hospitals here with the hospital mortality of some other countries.

	Period.	Delivered	Deaths per cent.
Germany, 47 hospitals[1] . .	1874-83	104,328	1.37
England, 10 hospitals[2] . .	1870-75	18,300	1.05
Vienna, I. Geburts. u. Gyn. klinik des Allgemein. krankenhaus[3]	1880-85	15,070	0.70
Vienna, II. Geburts. u. Gyn. klinik des Algemein. krankenhaus[4]	1882-85	8,355	0.52
Paris, Maternité[5]	1876-82	1,223	0.49

We shall have little cause for congratulation if we compare the records of our lying-in hospitals with those of the 47 German hospitals collected and published by Professor Dohrn. These hospitals, although dealing with an immense number of women and making use of them, as a rule, for purposes of instruction, present a record twice as good as our own. The English hospitals, whose records are given by Tait, even ten years ago presented a very much better showing than ours do to-day; and when we see the really astonishing results achieved in the obstetrical clinic of the General Hospital in Vienna, where under one roof more women are delivered in a year than in all the hospitals of the United States, we have still greater reason for dissatisfaction with what we have done in this direction, especially as there can be no good reason why we should occupy such a disadvantageous position in this international comparison, for with our greater wealth and the superior physical and mental condition of our populace, as compared with the peasantry of Europe, we should in every lying-in hospital strive, at least, to equal the results obtained by Tarnier in 1884, when, in the Maternite, he had 1000 successive accouchements with but a single death.[6]

Finally, in order to determine the relation that hospital mortality bears to the mortality of general obstetrical practice, we are confronted by the necessity of fixing a normal death-rate after childbirth, of knowing how many women die during or after labor in a large city; for to make the comparison with hospital results a just one, we must have in both cases the same environment.

The almost insuperable difficulty of determining the exact mortality of obstetrical practice in a large community will be at once apparent. If we consult the city's official record of deaths, we may be sure that many of those which are attributed to pyæmia and septicæmia really occurred during the puerperium, and that often a death directly connected with childbirth will, from ignorance, carelessness or design of the attendant, be ascribed to some other cause. The experience of the Registrar-General[1] of England in 1882 will be interesting in this connection. In that year there were reported, without further specification, 413 deaths from septicæmia and pyæmia, and 430 deaths from peritonitis, of women of childbearing age. A careful inquiry developed the fact that of the first group (413 deaths) 123 were due to childbirth, and that of the second group (430 deaths) 179 followed childbirth; in both groups of cases more than half the inquiries remained unanswered. This addition to the number of deaths after childbirth raised the mortality among the women who had been delivered in 1882 by 0.1 per cent., making the death-rate for the year throughout England 0.5 per cent. We may realize, therefore, how little reliance is to be placed upon official records if we would learn the true death-rate in obstetrical practice in a large city, where many of the women in labor fall into the hands of ignorant midwives or of physicians not much more skilful. I may as well at once assert my belief that this death-rate will closely approximate, if, indeed, it does not exceed, 1 per cent. of the women confined; but as there will be many, from the days of Le Fort to the present time, who will dispute the truth of this statement, it becomes necessary to support it by proofs that, to me at least, are convincing.

If we are unable to look for these proofs in our own official records, we have, nevertheless, several methods[2] at our command by which we may obtain the information desired. We might, as Tarnier once did, ascertain the number of women of childbearing age who had died in a certain district, and if by the record of births it was shown that any one of these women had given birth to a child within a month of her death, the death might be ascribed to childbirth. This method, if the record of births and deaths be reliable, can be depended upon to give a fairly accurate idea of the number of deaths from all causes after childbirth. We might, on the other hand, consult the records of other cities or countries which we have reason to believe more accurate than our own, or we may learn the results of the private practice of obstetricians who have attended a large number of women and have kept a careful record of their cases. Again, we might adopt McClintock's[3] plan in order to obtain the number of deaths from all causes after childbirth, including those from non-puerperal causes, as such deaths must sometimes contribute to raise the mortality of hospitals. Collecting the results of the house practice of nine reliable physicians in 16,774 cases, McClintock found that more than a quarter of the deaths after childbirth were due to non-puerperal causes. If, therefore, 25 per cent. is added to the number of deaths appearing in a city's

records as due to childbirth, a fair idea of the total mortality among puerperal women will be obtained.

Employing Tarnier's method, in Glasgow and Edinburgh, Duncan[1] found the mortality among women after childbirth to be 0.93 per cent. Applying McClintock's method to the records of Paris, St. Petersburg, and Dublin, he found the mortality in those cities to be respectively 0.83, 0.89 and 1.16 per cent. of women confined. By a careful analysis of the records preserved in the Health Department of New York City, Lusk[2] found that 1.17 per cent. of the women confined in New York, during the years 1868–75, died as a consequence of childbirth. In the Duchy of Baden there were delivered, in the year 1884, 54,996 women.[3] Of these, 0.4 per cent. died of puerperal fever; 0.7 per cent. died after the performance of the different obstetrical operations, from accidents during labor, or from eclampsia; but the cause of death in some of these cases was undoubtedly septic poisoning, and they would consequently be included in the first percentage, so that the death-rate cannot be estimated by adding these two percentages together, which would make 1.1 per cent., but the death-rate is probably not less than 0.9 per cent. of the women confined, and this in an agricultural district containing no very large towns and with a comparatively healthy and prosperous population.

A. H. McClintock,[4] speaking before the British Medical Society, gave the results achieved in private obstetrical practice by nine reputable physicians, men of no mean skill and intelligence, as the following list will show:

A death-rate of 0.95 per cent

These figures certainly seem to justify the assertion that, at least, 1 per cent. of the women delivered in a large city will die. If one hesitates to admit that such is the mortality associated with what is usually regarded as a simple physiological process, what shall be said of the death-rate attending confinement in the lying-in hospitals of this country, which is more than twice as great as that of general practice, and in individual instances four and five-fold greater?

The title, charitable, can be conferred upon many of these institutions only by the followers of Malthus; but as their existence has become a necessity in all populous communities, a necessity which will become more pressing as the population of this country becomes more densely concentrated at certain points and the poverty of the lower classes increases, surely common humanity demands that they be controlled by State or municipal supervision, in order that they may fulfil the ends for which they were intended—that they may truly afford aid to a woman at a time when it is most urgently needed—and that they may not, as many of them do to-day, make childbearing as dangerous to the woman as an attack of typhoid fever or the performance of laparotomy.

CASE OF DERMATITIS HERPETIFORMIS OF THE PUSTULAR VARIETY.

BY LOUIS A. DUHRING, M.D.,

[illegible]

IN reporting the notes of a case of a rare disease no apology therefor need be made, for the reason that any information on the subject must prove valuable. The disease under consideration being of infrequent occurrence, and, moreover, constituting a new field of observation, concerning which there seems to be some diversity of opinion among dermatologists, is for these and other reasons worthy of close investigation. With our present knowledge every case encountered is entitled to a place on record, with the hope that as the published data accumulate we shall better comprehend the process.

The following case was under my observation at intervals during a period of five years. At the time the disease seemed to me incomprehensible on account of the peculiar lesions, their behavior and course, which were altogether different from those of any affection with which I was familiar. Classification of the disease was beset with difficulties, as the original notes testify, and the case was regarded as an anomalous one—as representing, perhaps, an undescribed disease. The several provisional diagnoses (of eczema? of ecthyma? of tinea circinata?) made from time to time show the resemblance of the lesions to those of well-known affections, and give an idea of the multiformity displayed. The case, moreover, is interesting as exhibiting a phase of this peculiar disease that has not been brought out in any of the cases that I have previously reported. These features will be referred to later.

The patient came under notice in 1874, and the following history is an abstract of the notes taken at that date. Daniel Welsh, fifty years of age, Irish, and a hostler by occupation. He had previously been subject to "prickly heat" during the summer about the trunk, and was so affected year before last, this attack having been followed by a much more serious disease of the skin similar to that, he states, with which he now suffers. He describes the eruption he had at that date as being pustular and vesicular, with intense itching and burning. The itching was intolerable, and the disease continued for three months. Crusting followed the formation of the pustules, which remained for some time, the process eventually passing off with scaling. He recovered in the autumn, and remained well six months, when the present eruption appeared. It continued throughout the summer, becoming better toward autumn, but it never left him entirely.

About a month ago it began to grow worse. It is now confined to the trunk, shoulders, and buttocks, and is particularly well defined upon the abdomen and sides of the thorax. The lesions are disseminated, but possess certain herpetic features, and consist of numerous minute, small and large pustules, with yellowish contents, in all stages of development. They vary much in size, some being no larger than pin-points and pin-heads, while others have attained the size of peas and beans. The latter are not acuminated, but are flat and spread out, although considerably raised above the surrounding healthy skin. In outline the larger ones, as a rule, are oblong or irregular, and angular, and have an herpetic, "puckered" appearance. The small recent pustules are not attended with any redness of skin, having no inflamed base or areola; but the larger and older ones are surrounded with a deep red areola of considerable size. There are no vesicles. [A week's observation proved that this eruption began as a well-defined pustule, and continued as such until a crust formed, which became detached in four or five days, leaving a pigmented base.] In addition to the pustules there is considerable pigmentation, of a reddish, dirty-yellowish, brownish hue, which is present here and there over the surface in a marked degree, and is a conspicuous symptom, being much greater and more persistent than with other similar inflammatory processes.

The disease at present is almost without itching, burning, or other annoying symptoms. The eruption, he states, comes out in crops, one scarcely disappearing before another makes its appearance, and in this manner the process is kept up from week to week and month to month.

Such was the condition when admitted to the Dispensary for Skin Diseases, April 28, 1874. He was placed upon external and internal treatment, the disease being then regarded as pustular eczema. During the following month under the use of iron and arsenic and varied external remedies the cutaneous lesions increased. A few weeks later minute pustules began to appear in a grouped, circinate, herpetic form, as in typical tinea circinata, the appearances resembling an exaggerated phase of this latter disease, so much so that it was thought it might possibly be due to a vegetable parasite, but the microscopic examination revealed nothing of this nature.

Itching and heat now began greatly to annoy the patient, and within a week some of the circinate patches increased in size until they became two inches in diameter. The pustules were minute and small, and hence the picture did not suggest herpes iris. Two weeks later the attack subsided and the lesions rapidly disappeared, but only to reappear immediately as a new crop, as before, in the form of numerous pin-point and pin-head sized pustules. The following week another crop, numbering thousands of lesions, invaded the trunk, accompanied with burning but no itching. This attack increased in extent and severity, but the lesions remained small, a few only being as large as a pea. Scales and thin crusts formed in large patches, and scaling and exfoliation set in. The skin became intensely itchy and hot, and he was unable to sleep, and was depressed and discouraged.

The patient now passed from under observation, having experienced no relief from the varied treatment which he had undergone. Five years afterward he again presented himself to me, still a sufferer with the same disease. An ointment containing sublimed sulphur one ounce, lard two ounces, and oil of walnuts two drachms, was now used, and with positive relief to the itching and burning, and with the remarkable result of causing the lesions rapidly to disappear. The inunctions were made with friction, as in the treatment of scabies. I subsequently saw him in several attacks, in one of which the pustules were herpetic and grouped, as previously, in a crescentic or more or less annular form, new lesions, moreover, showing themselves on the periphery of the patches, accompanied with much itching. The ointment referred to was again (and on later occasions) employed with the same admirable result, the patient stating that during the many years of his suffering this was the first and only remedy that had in any degree benefited him. He spoke of the relief to the subjective symptoms as being instantaneous, and looked forward to a speedy permanent cure. Whether or not this occurred I am unable to say, as shortly afterward he ceased attending the clinic.

The interesting points of the case are, first, that during the period I had the patient under observation the lesions remained pustular, being at times minute (not larger than pin-points and pin-heads), and on other occasions larger,—the size of peas and beans. At all times, even when the eruption might be regarded as being disseminated, they possessed herpetic features, being either (when of large size) seated upon an angry-looking, drawn-up, puckered base, or (when small) grouped in close proximity, sometimes in an annular form, as in tinea circinata and herpes iris. As characteristic of the disease, may be mentioned the disposition of the eruption to appear in crops; the pigmentation of the affected skin; the obstinacy of the process to treatment; the tendency to relapse; and the long duration of the disease as a whole. Finally, the subjective symptoms were peculiar, being at one time marked and at another time almost absent. The variations on this point were remarkable if the statements of the patient are to be relied on. The fact, however, of the lesions being pustular would account for the comparative freedom from itching, this symptom, as is well known, rarely accompanying pustular lesions of any kind.

ACCIDENTS ACCOMPANYING THE USE OF THE A.-C.-E. MIXTURE.

By W. H. SHARP, M.D.,

[illegible], W. VA.

In The Medical News of January 8th, Dr. John H. Packard relates an accident following the use of the A.-C.-E. mixture. He speaks of the few recorded cases of fatal or alarming results from its use. It has happened to the writer to see alarming symptoms accompanying its administration, which I will briefly relate from memory.

In the spring of 1865, while stationed at the U. S. A. "Summit" House General Hospital, Philadelphia, the staff were performing an amputation of the leg. At the suggestion of Surgeon Joseph Taylor, in charge, the A.-C.-E. mixture was used. The anæsthetic was administered by Surgeon A. A. Leavitt, Executive Officer of the Hospital. During the operation, the patient's respiration failed. The condition became so alarming that the operation was temporarily discontinued, and all present turned their attention to restoring the patient. Artificial respiration, cutaneous excitation, and inhalation of fumes of ammonia, fortunately, were successful. The operation was then finished, with the patient only partially unconscious. For many years I had not used this mixture, using either ether alone, or the mixture of ether two parts, chloroform one part, by weight; or, rarely, chloroform alone.

During the past two years, I have on several occasions used the A.-C.-E. mixture with gratifying results, being led to use it again by the favorable reports given by various authorities. During the summer of 1886 I was removing cancerous mammary and axillary glands—assisted by Drs. Martin and Chesney of Cairo, West Virginia. To Dr. Chesney was intrusted the administration of the anæsthetic, which was the A.-C.-E. mixture. During the operation I had requested him to discontinue the anæsthetic, as the patient was sufficiently under the influence. This he did; he had his finger on the pulse, and devoted his entire attention to the patient's condition. The mammary gland had been removed—care being taken by Dr. Martin to prevent entrance of air into the veins. I noticed the extreme pallor of the patient's face, and simultaneously Dr. Chesney said the pulse had failed, so as to be inappreciable. I immediately placed a bottle of nitrite of amyl to her nostrils—respiration was good. Asking Dr. Martin to hold it there, I prepared a hypodermatic syringe with 20 m. of tr. digitalis, and injected it in the precordial region. Dr. Martin meantime announced a slight recovery of pulse. I next administered several syringefuls (hypodermatically) of whiskey, and we had the pleasure of seeing the patient rally from this heart-failure—due, I think, to the depressing influence of the chloroform. It was carefully administered—with a sponge in a cone—*i. e.*, a towel stiffened with a sheet of paper in its folds; the sponge was held in its place in the apex by transfixing with long pins to prevent it falling down on the patient's face. The chloroform and ether were of reliable manufacture. It afterward developed that at this time the liver was involved in secondary cancerous inflammation, from which the patient succumbed a few weeks after recovery from the operation.

In the administration of ether alone, it has been my fortune to see on several occasions alarming symptoms due to the failure of the respiratory function. Several years ago Dr. Harris, of Parkersburg, West Virginia, and myself, were operating for laceration of the cervix uteri, assisted by Drs. Campbell and Hunt, of that city. The patient was in the semiprone position, Dr. Hunt administering the anæsthetic. She had been fully under its influence some twenty minutes (pure sulphuric ether being used), when Dr. Hunt found that respiration had ceased. He immediately drew forward the tongue, and he and Dr. Campbell endeavored to excite respiration. Not succeeding promptly, I aided them by artificial respiration; our joint efforts being of no avail, I suggested to Dr. Harris to withdraw the speculum and aid us. By this time the scene was alarming; her female relatives present were shrieking, "She's dead," and it looked as if it was too true. Dr. Harris seizing her by the legs elevated the body. Almost immediately a gasp, and again a second, and the crisis was over. After respiration was fully restored, the operation was completed without further anæsthesia.

On several occasions I have seen under ether the respiration suspended, requiring the drawing forward of the tongue and efforts made to excite respiratory action, which each time promptly succeeded; once from the effects of the ether and chloroform mixture not being as carefully watched as it should be, while a friend and myself were effecting delivery of an impacted transverse fœtus.

Dr. Packard speaks of the advisability of having "the administration confided to an assistant who should carefully watch its effects, paying no attention to anything else." Very true! but in general practice in the country this is impossible to secure: most frequently but two physicians are present, and the services of each are needed in the operation. Oftentimes the operator is alone—the assistants are such neighbors, male or female, as have the nerve to witness an operation, and the surgeon has to keep an eye on the patient's condition, as well as operate. This is unavoidable. It has been my duty to have to operate for fracture of the skull with depression in a child with no assistants except laymen; or again to amputate at the shoulder-joint under similar conditions, or to use anæsthetics repeatedly in difficult labor cases, with aid of one or two sensible women. It cannot be avoided, and the operator can, at least, only select the safest anæsthetic, enter upon his operation, exercising all vigilance possible, by instructing the layman intrusted with the anæsthesia what to look after, and then feel that if any accident occurs, the assuming of the responsibility is unavoidable to the man who has "the courage of his convictions." Still we must all feel that when the patient is fully anæsthetized there is a possibility of death ensuing; fortunately rare, but still possible.

In country practice it is not possible to go around "*cap-a-pie*," as described by Dr. Packard, with galvanic battery, etc., but we can take with us brandy, ammonia, tr. digitalis, and nitrite of amyl and a hypodermic syringe ready for use. While I have not seen any unfavorable results from chloroform alone, the conviction has been arrived at that it should not be used, except at times, to bring the patient under anæsthesia, where the struggling and excitement from ether render full anæsthesia from that agent very tardy or likely to fail, to be replaced by the ether as soon as the desired object is obtained.

Many fatal accidents are never reported. I know

of one death from ether occurring in Baltimore several years ago, where an operation was being performed for a uterine fibroid, in a patient very greatly reduced by hemorrhage. This, I believe, was never published. Again some years ago, a friend in one of our towns in West Virginia, told me of a fatal case from chloroform happening to him. I asked him if he had published an account of it. "No, indeed, I felt too badly, and besides, it was published enough, without my reporting it," was the substance of his reply. I have been told of others occurring in military practice during the late civil war, which have never been reported.

Death from shock even after trivial operations occasionally occurs; see case reported by Dr. Tompkins, of Charlestown, West Virginia, in the *Medical Record*, last year, in which death from shock followed excision of the uvula. A few days ago I saw alarming attacks of syncope, the result of a hypodermatic injection of one-twelfth of a grain of morphia for neuralgia, in a lady subject to such attacks. From such cases, we can only wonder that accidents do not more frequently occur.

A LARGE RETINAL VEIN CROSSING THE MACULAR REGION.

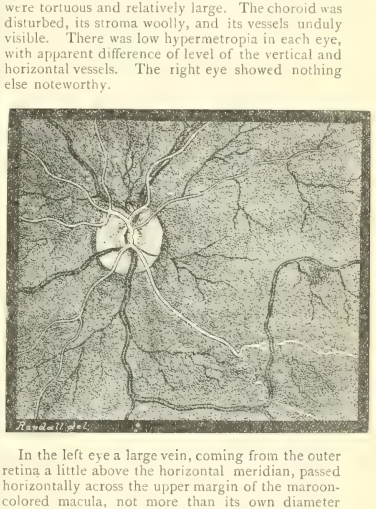
BY B. ALEX. RANDALL, A.M., M.D.,
OF PHILADELPHIA.

IN describing the vessels of the human retina, almost all authorities state emphatically that no vessels of notable size traverse the immediate neighborhood of the macula; and, to judge from the barren literature of the subject, exceptions to the rule would seem almost unknown. As it has been the writer's fortune to see several exceptions, he hopes that a record of the matter may have for others some of the interest which the cases have for himself.

The macular region is, of course, extremely vascular, as has been frequently shown, and as any one can see for himself by entoptoscopic methods; but these vessels are generally the most minute capillaries. Ayres[1] has shown in his drawing of this network, that one of his eyes has a rather larger vessel, discoverable with the ophthalmoscope, crossing the area usually non-vascular. Yet this is almost capillary in size, and it is safe to say that it would never have been seen objectively had not its presence been first subjectively proven. No note of a similar arrangement has to my knowledge been recorded by another observer.

The case of arterio-venous anastomosis which has been reported and figured by Mr. Marcus Gunn,[2] (and which I had the pleasure of studying at the meeting of March, 1884, of the British Ophthalmological), was notable also by reason of the unusual proximity to the macula of two conspicuous veins; and another closely similar case (not yet reported) which I observed in the practice of my colleague, Dr. Heyl, showed vessels of considerable size in the macular region. In neither of these, however, was the macula intruded upon, and the following case seems to be unique.

A young lady of sixteen was examined and treated by my colleague, Dr. de Schweinitz, and myself, in October, 1885, on account of trouble with her eyes. There was blepharitis, which could be controlled but not cured by topical treatment, and considerable brow-pain at near work; no other asthenopic symptoms. The vision was normal and equal in the two eyes, the accommodation apparently subnormal (8 D.); there was insufficiency of convergence of about eight degrees by the v. Gräfe test; little or no astigmatism. The ophthalmoscope showed each nerve small, oval, and surrounded by an absorbing pigment ring. The upper and lower disk-margins were veiled by retinal haze and striation, and the retinal vessels were tortuous and relatively large. The choroid was disturbed, its stroma woolly, and its vessels unduly visible. There was low hypermetropia in each eye, with apparent difference of level of the vertical and horizontal vessels. The right eye showed nothing else noteworthy.



In the left eye a large vein, coming from the outer retina a little above the horizontal meridian, passed horizontally across the upper margin of the maroon-colored macula, not more than its own diameter above the fovea; then, turning downward, it descended vertically to join the lower temporal vein about two disk diameters below the macula. Two branches—small indeed, but larger than are usually seen in the macular region—joined the vein just before and just after it crossed the maroon area, the one nearer the optic disk trenching upon the lower inner border of the macula. No other anomalies were noted. The condition was carefully and repeatedly studied and drawn by Dr. de Schweinitz as well as myself.

It may be added that the hypermetropia proved to be + 0.9 D. without measurable astigmatism, and that with the appropriate glass the patient has done excellently. There is no subjective recognition of

[1] Archives of Ophthalmology, xi. p. 476, 1882.
[2] Trans. of the Ophth. Society of the United Kingdom, iv. p. 156, 1884.

the vessel except by entoptic methods; then the large, dark band is seen immediately below the fixation point, in total contrast to the usual picture of the delicate network seen in the right eye. Of her family, the father is myopic, the rest slightly hypermetropic; none show any similar anomaly.

Some five years ago, when I began to study the macula as an essential part of the ophthalmoscopic examination in every case, I saw a child whose left macula was crossed by a small vessel (a vein, if I recollect aright) which was touched by the tiny reflex of the fovea, and seemed actually to dip into its depression. I never saw the case again, and had no one by to confirm the observation—which was made in the haste of full dispensary work and not recorded at the time. Much doubt must, therefore, attach itself to the case; but I can so vividly recall the appearance that it is difficult for me to discredit my recollection of it, and I venture to note it here.

HOSPITAL NOTES.

THE TREATMENT OF PNEUMONIA IN THE PHILADELPHIA HOSPITALS.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

DR. PEPPER reduces the initial high fever in cases of pneumonia in his wards (if, as unfortunately rarely happens, the case has been admitted just after the onset) by antipyrin or by the external use of cold water. It was for this, accompanied with severe pain, that venesection was formerly used; and he still advises its use at this earliest stage if high fever returns promptly after reduction by the above remedies. They will often produce a favorable impression, however, with less risk. Throughout the disease the fever must be carefully watched and often requires to be promptly reduced. Sometimes large doses of quinia—as thirty or forty grains given in two doses at intervals of four hours—will do this; but antipyrin or thallin or antifebrin is so much more prompt and certain that he prefers using one of them, and especially antipyrin, for the occasional control of hyperpyrexia, while giving continuously a moderate amount of quinia, say ten or twelve grains daily. Quinia meets several indications in pneumonia, and he nearly always gives it, adapting the dose to the grade of disease and special conditions of the patient. As the stomach must be very carefully guarded in pneumonia and everything avoided that might irritate it, it is often better to give quinia by the rectum.

He is more in the habit of using aconite than veratrum, but one or the other of these powerful and reliable arterial sedatives should be used during the early days of the attack, given in frequent and moderate doses so as to produce safely their physiological effect by lowering the pulse rate, relaxing the system and aiding in reduction of fever. Later, if the pulse loses force or after the area of the disease has become defined, the indication for arterial sedatives has usually passed.

Not only must care be taken to avoid irritation of the stomach, but in many cases especially in the early stage there is much gastro-hepatic congestion and irritation present, and here it is important to limit ourselves to relieving this by short courses of small doses of calomel with or without soda, using meanwhile quinia by the rectum to control fever. It is especially in these cases that aconite is preferable to veratrum on account of its less tendency to irritate the stomach. After the disease is developed, ammonium carbonate is preferred to stimulate respiration and favor resolution. It is usually given in single emulsion and in doses of five grains every two or three hours for an adult.

The diet must be adapted carefully to the state of the stomach. It should be liquid throughout and for the first two or three days should be very restricted, but after that may be more free and concentrated if well received. It is extremely important that the patient be not allowed to make any exertion. Rigid rest must, indeed, be insisted upon, for pneumonia is one of the diseases in which sudden death is apt to occur from any improper effort, as even of rising to sit upon a commode by the bedside.

The indications for alcoholic stimulants are drawn from the state of the circulation and nervous system. Many cases do well without any stimulus from beginning to end; but on the other hand the signs of cardiac failure or of failure of nervous force call for alcohol, which may be required to be given freely. Of course, it is to be adapted, as to amount and mode of administration, to the state of the stomach. In general a layer of cotton or wool batting stitched inside of the merino undershirt, over the outside of which a layer of oiled silk is placed, is preferable to poultices. The latter must be made skilfully to be pleasant; they must be changed frequently, and unless this changing is done with great care there are both fatigue and risk involved. Of course, the above remarks apply solely to croupous pneumonia.

DR. OSLER in hospital practice recognizes two groups of pneumonic patients—the alcoholic and the temperate. A majority of the former die in spite of all treatment; a majority of the latter get well with any, or with no, treatment. That the mortality from pneumonia in the large, general hospitals is uniformly above twenty-five per cent. is due to the fact that to them are admitted the debilitated paupers of the community with systems undermined by exposure and drink, and in no state to combat an acute disease. Alcoholics with renal inadequacy rarely survive pneumonia.

When the disease is limited, the fever moderate, and the pulse good, a dilute acid mixture is given with Dover's powder to allay the pain and the cough. Cotton wadding, or, if the patient prefer, light poultices are applied to the affected side. Blisters are never used.

As the disease can neither be cut short nor essentially modified by any remedies we at present possess, in severe cases we have to watch and meet the tendencies to death.

First. Heart failure from engorgement of the right chambers, and the lesser circulation, indicated by cyanosis and urgent dyspnœa. Free venesection can alone meet this danger, and should be performed on the first signs of cyanosis, with failing heart. Good results have followed the removal of from eighteen to twenty-five ounces of blood. It is often left too late, and to be efficacious should be done early. It is not always successful. Two cases bled this session died.

Second. The fever, against which quinine, antipyrin,

and antifebrin are employed; but the action of antipyretics in pneumonia is more uncertain than in other acute fevers. Cold sponging and the cold pack are more effectual when the temperature becomes dangerously high.

Third. The increasing debility, systemic as well as cardiac, demands stimulation and careful feeding. A majority of the fatal cases die of progressive heart failure, against which alcohol is given freely. Digitalis is also employed, but the full tonic action of this medicine is rarely seen in the weak heart of fever. Camphor and strychnine are useful in this condition.

Of medicines, carbonate of ammonium is freely given. Opium is used to allay the early pain and to quiet the cough. Extensive bronchitis with liquid expectoration is a contraindication. Arterial sedatives are not much employed, but when the cases are seen early, aconite is sometimes given. In the mild cases they are not often needed, while in the more severe ones they may be positively injurious. Expectorants are rarely called for, and when used the ammonia and nux vomica fulfil the indications. A milk diet is given, varied as occasion arises.

Jefferson Medical College Hospital.

Dr. Bartholow observes that the treatment of pneumonia (acute croupous pneumonia) must be adapted to the varying conditions of its several stages. The therapeutical stages may thus be—congestion, exudation, crisis or lysis, resolution. When the proper period for crisis or lysis passes without the occurrence of the phenomena indicating it, only two terminations can be expected—subacute or chronic pneumonia; death.

At the onset, when the chill occurs, he gives a full dose of quinine (15 to 20 grains) and morphine (half a grain). He does not claim that this may abort the disease, although he believes it does sometimes effect this, but that it certainly does limit the extent of the congestion then taking place. During the stage of congestion and commencing exudation he employs two remedies chiefly: aconite and opium. Of the former, two drops of the officinal tincture; and of the latter, ten drops of the deodorized tincture, are given every two or three hours; double these amounts being administered at the first dose. When exudation has occurred, for the aconite ammonia is substituted. He prefers the carbonate dissolved in the liquor ammonii acetatis, ten grains to the ounce, of which a tablespoonful every three hours is given.

During the first and second stages, should there be wakefulness or delirium, or the temperature continue high (at 105° or 106° F.), Dr. Bartholow prescribes chloral in fifteen grain doses, three or four times in the twenty-four hours. Indeed, he has found that cases do better with than without chloral, and this, probably, because chloral has a solvent effect on fibrin and fibrinous exudation. As it, also, lessens body-heat, and quiets restlessness, which is only less exhausting than delirium, it becomes directly useful as a remedy for these important elements of the morbid complexus.

As the crisis occurs, or the lysis begins somewhere from the fifth to the eleventh day, attempts at resolution that might otherwise prove abortive, may be changed into a well-defined crisis by the timely administration of quinine or alcohol in an efficient dose. The indication for the use of one or the other of these remedies, consists in the appearance of some one of the critical phenomena, without the concurrent presence of the others. A copious sweat, an attack of diarrhœa, the sudden return of the chlorides to the urine, the appearance of herpes on the lips, etc., are, of course, the usual objective evidences of the crisis. In the more serious cases, one of these signs may appear, and yet the attempt at resolution fail. It is then that the vital forces need the aid of one or both of these remedies to accomplish the revolution in the pathological process; then quinine, if the dominating factor is elevated temperature; or alcohol, should the cardiac energy appear insufficient; or both, if these conditions are combined.

The persistent use of quinine or of alcohol, according to Dr. Bartholow, is not to be commended. Quinine increases the digestive weakness, and alcohol, in any considerable quantity embarrasses the circulation and impairs the oxygenation of the blood. Nevertheless, alcohol has a distinctive place in the treatment of alcoholic pneumonia. The pulmonary inflammation is often masked by the delirium tremens which is excited by the sudden withdrawal of the accustomed stimulus, and the failure of the nutrition; and, hence, under these circumstances, the alcoholic food must be freely supplied.

As regards counter-irritation, he is clear that only a mild irritation is proper; for whilst this, by a reflex action, stimulates the vasomotor system, and thus lessens congestion, severe counter-irritation, on the other hand, depresses the trophic system and hinders rather than promotes nutrition and repair. A succession of mustard plasters, each applied only long enough to redden the skin slightly, is the best form of counter-irritant. Stupes of turpentine are cumbrous, oppressive, and disagreeable, and blisters are unsuitable, unless applied long enough merely to act as a rubefacient. The counter-irritant or rubefacient cone now made for topical applications, is a very convenient, even elegant, preparation for this purpose.

Venesection continues to be a *vexata questio*. In the old antiphlogistic days, bleeding was so completely overdone, that any merit it has was overwhelmed in the general condemnation. There are, however, two conditions of the circulation in pneumonia, in which a timely bloodletting is of great value: at the outset in a vigorous subject, when congestion is increasing in depth and extent; and at the approach of the crisis, when the heart labors in consequence of overfulness of the veins, and ischæmia of the arteries.

The necessity for close attention to the state of the nutritive functions is distinctly recognized. As the gastric juice in cases of pneumonia is deficient in the constituents required for the formation of peptones, Dr. Bartholow is careful to supply them with the aliment.

The Pennsylvania Hospital.

In the treatment of acute pneumonia, Dr. A. V. Meigs ordinarily pursues a certain plan which is modified according to the needs of each particular case. The patient is confined rigidly to bed, and, if advanced in years, it is important even that the bed-pan and urinal be used. Food is administered at regular intervals, and

if the case be one of severity it should be liquid, and is best given every two or four hours. In severe attacks milk and beef-tea are given alternately every two hours, three or four ounces at a time. Medicines are given on a plan corresponding with the system upon which nourishment is administered, and usually are taken a quarter of an hour after food; thus the longest possible period of undisturbed rest is afforded the patient. A careful attention to details certainly in the long run conduces much to the recovery of patients. No stimulant is given in mild cases, particularly in young persons, so long as they progress with seeming safety. In severe attacks the patient is freely stimulated, from two to twelve ounces of whiskey, or in rare instances even more, being given in twenty-four hours. It is best given in the milk. Ordinary medicinal treatment is the administration in pill form every four hours of digitalis, gr. ½; opium, gr. ⅛; and quinine, gr. j. In severe attacks this is suspended and ammonia substituted, or the two are given in conjunction. The most reliable form of ammonia is the carbonate, of which five grains are given every two to four hours, according to circumstances, or there may be administered at the same interval a drachm of the aromatic spirit, or half an ounce of the solution of the acetate.

As yet it has not been his fortune to meet with a case in which he has thought it advisable to bleed, although he believes it to be good practice, if done judiciously in the early stage.

The application of dry cups is a measure often attended with great relief of the suffering, and benefit to the patient, in the early stage of the disease, particularly if the attack is complicated, as is very commonly the case, with much pleuritic pain. From eight to twenty cups are usually applied.

With regard to external applications, he uses no poultices, which are difficult to keep in place, and once begun are hard to get rid of, and become exceedingly troublesome when the sweating stage comes on. Sometimes he has cotton or wool, preferably the latter, sewed upon the inner surface of the shirt.

This is not the place to dilate upon the utter inadequacy of any known treatment to avert the fatal result in some of the more sudden and violent forms of the disease. A careful and patient pursuance of the plan detailed has proved more satisfactory in Dr. Meigs's hands than any other in the management of such cases as have been in his charge in the Pennsylvania Hospital, if they seemed amenable to any treatment.

PHILADELPHIA HOSPITAL.

DR. TYSON recognizes that in the class of patients admitted to this hospital the sthenic form of pneumonia requiring vigorous antiphlogistic measures is rarely seen. He rarely, therefore, practises general bloodletting, but wet-cupping over the affected lung is frequently resorted to. The cupping is followed by jacket poultices, which are continued until the case terminates favorably or unfavorably. Blistering over a liberal area is sometimes substituted for the cupping.

The antipyretic measures used are either digitalis and quinine in full doses, or quinine and the fluid extract of veratria, the latter in five drop doses every two hours, until the pulse is decidedly reduced. Digitalis is used in cases where debility is conspicuous, and requires to be combated. It is given in doses of fifteen drops of tincture, or two fluiddrachms of the infusion every three hours.

From the onset stimulants are freely used, and half-ounce doses of whiskey are given every two hours, or hourly; while it is not unusual to give an ounce of whiskey every hour. It is generally given in the form of milk punches.

Stimulant expectorants are given only when the exudate begins to soften, as indicated by the *crepitans redux*, and cough tending to become loose. Carbonate of ammonium is generally used in doses of from five to ten grains. In cases requiring less stimulation, the ammonium chloride is prescribed in fifteen grain doses. An old practice of the hospital was to give the officinal liquor potassæ as an expectorant, with the idea that it "thinned" the viscid secretions. There is reason to believe that potassium carbonate has a similar effect.

DR. J. C. WILSON treats his cases of lobar pneumonia in the wards of this hospital symptomatically. The patients, who are drawn from the pauper class or those closely bordering upon it, are not often young, almost always debilitated by destitution or previous disease, frequently the subjects of chronic alcoholism. A considerable proportion of them are admitted at the close of a more or less prolonged debauch. Very few cases of primary pneumonia develop in the wards. The patients are commonly received in the first week of the disease, but very rarely so early as the first day. Neither general nor local bloodletting is practised. The plan usually pursued is as follows:

The patient is bathed and put to bed. If there be no reason to depart from the rule, a mild mercurial purge is at once administered. In case of diarrhœa, great exhaustion, or at an advanced period of the disease, it is omitted. A small dose of opium or a hypodermatic injection of morphine follows after a time, and is repeated occasionally during the attack as may be required to control pain or induce quietude and sleep. After the bowels have been relieved a single large dose of quinine, rarely less than xvj or more than xx grains, is given. From this time until defervescence quinine is not again used except in response to some well-defined indication such as excessive pyrexia. Ammonium carbonate in v grain, less frequently vijss, or x grain doses, is given every second hour, in many cases, throughout the attack. Alcohol is freely used, the frequency and amount of the dose being regulated by its effect upon the heart and nervous system, the total quantity in twenty-four hours seldom exceeding twelve fluidounces of whiskey. In favorable cases with moderate fever and especially in the absence of a previous history of addiction to drink, it is used sparingly. Nevertheless all the cases receive a certain amount of alcohol. Pyrexia, when moderate, demands no special therapeutic measures; when intense, it is treated by icepoultices to the chest, cold compresses, the cold pack, antipyrin, or large doses of quinine. Digitalis, veratrum, belladonna, and aconite are very seldom used and then only to fulfil special therapeutic indications. Pilocarpine is not regarded as curative. The diet is light, bland, nutritious, and of moderate amount. Turpentine stupes are repeatedly applied, sinapisms occa-

sionally, blisters never, save in cases of delayed resolution. Poultices are only exceptionally employed, a light jacket lined with cotton batting or fine carded wool being found more comfortable, more convenient, and fully as useful.

Upon the occurrence of defervescence alcohol is rapidly decreased in amount, the diet increased, solid food added, and quinine in smaller doses administered. It is usually advantageous to give iron or arsenic for a time. Flying blisters, or the external use of iodine and small doses of potassium iodide may be useful in delayed resolution. Convalescent patients are not kept long in bed, but are encouraged to sit up and move about as soon after complete defervescence as their strength will permit.

Despite the greatest care in the management of this disease in the Philadelphia Hospital, the death-rate, owing to the character of the patients, is high.

MEDICAL PROGRESS.

Antiseptic Obstetrics in the Boston Lying-in Hospital.—The following is the routine practice described by Dr. Richardson, of Boston, in an article in the *Boston Medical and Surgical Journal* of January 27, 1887.

On her admission to the hospital, if time allows, the patient is given a bath. In every case the genitals and the surrounding parts are washed with a solution of the bichloride of mercury (1 : 3000). A basin containing the same solution and a nail-brush is placed on a stand side of the bed. The physician and nurse in attendance disinfect their hands every time they have occasion to examine the patient or touch the neighborhood of the vulva. The examining finger is smeared with an ointment made of one part of the oil of eucalyptus and seven parts of vaseline. A vaginal injection of the corrosive sublimate solution is given at the beginning of labor, and this is repeated, when circumstances permit, at the end of the first stage. As the head distends the perineum and is expelled, the parts are kept clean, when occasion requires, by the use of charpie dipped in the mercurial solution. After the birth of the child no undue haste is made to bring about the expulsion of the placenta. This is effected, if possible, by Credé's method of expression, great care being taken not to introduce the hand within the vulva, if such a procedure can be avoided. The perineum is carefully examined, and if there is sufficient laceration to require sutures the parts are washed with the corrosive sublimate solution, after which the edges are brought together by means of carbolized catgut sutures, some powdered iodoform being subsequently applied over the seat of the laceration. The vaginal injection is repeated, and the antiseptic pad is applied, being pinned at the four corners to the abdominal binder by means of safety-pins.

During the convalescence the pad is changed as often as occasion requires, the nurse taking care to disinfect her hands thoroughly before removing the pad. Each time the pad is changed, the parts around the vulva are sprayed with the mercurial solution by means of a hard-rubber sprinkler, made by the Davidson Rubber Company to fit their syringes, which are the ones used in the hospital. It is usually necessary to change the pad during the convalescence about as frequently as it was formerly necessary to change the napkins which the patient wore before the pad was introduced. If it is necessary to use a catheter to empty the bladder, that instrument is, of course, to be disinfected, as well as the hands of the person using it. Care is also taken, before introducing the catheter, to wash the parts in the neighborhood of the meatus with the disinfectant, in order to avoid the introduction of blood, vaginal or uterine discharges within the urethra.

The use of the antiseptic pad is continued until the patient sit up, or until all danger of septic infection has passed. Whenever the mother has given birth to a putrid child or a partially decomposed placenta, an intrauterine injection of the corrosive sublimate of the same strength is given at the close of the labor, in addition to the vaginal one already alluded to. Should it be deemed advisable to give an intrauterine injection, it is safer, after washing out the uterine cavity with the mercurial solution, then, without removing the nozzle of the syringe, to inject a few ounces of a solution of carbolic acid (1 : 40) of the same temperature (112°). By this method any danger of mercurial poisoning (which sometimes, though rarely, follows the use of corrosive sublimate as an intrauterine injection) is avoided.

In case it is found necessary to use instruments during the delivery, care is taken to disinfect them by means of a solution of carbolic acid (1 : 40). The same solution is used for the needles, needle-holder, etc., which may be required for sewing up any perineal laceration. Carbolic acid is used in these cases, in preference to the bichloride of mercury, on account of the corrosive action of the latter on the instruments. If, for any reason, it is necessary to introduce the hand within the uterine cavity, great care is taken thoroughly to disinfect the arm as well as the hand of the operator.

The antiseptic pad is made as follows: A strip of Canton flannel (19 by 4½ inches) is placed upon a table, with the soft side uppermost. On the centre of this is laid a piece of carbolized cotton (11 by 4½ inches), about half an inch in thickness when not compressed. Over the centre of this is a piece of oiled muslin (9 by 4 inches). On this is placed the pad itself, which is made of what is known as absorbent scrap or waste done up in cheese-cloth, and of a size sufficient to cover the oiled muslin, and about half an inch in thickness, before it is wet or compressed. This pad, before using is dipped in a solution of corrosive sublimate (1 : 3000) and dried. Whenever a pad, with its binder, is removed and a fresh one substituted, the old pad, including the Canton flannel, oiled muslin, etc., is burnt up.

Since the fall of 1885 the above has been the method in which antiseptics have been used in the hospital. The results have demonstrated, beyond the possibility of a doubt, the great value of such prophylaxis."

The Preparation of Solutions of Corrosive Sublimate.—Angerer, of Munich, has observed following the use of undistilled water in dissolving corrosive sublimate, an insoluble precipitate which Fürbringer has shown to be different oxides of mercury produced by the alkaline carbonates of the water.

In the Surgical Policlinic of Munich, Fürbringer's analyses were repeated, and it was found that light,

warmth, and the presence of air greatly influenced the precipitation, and that with the city water of Munich a precipitation to an amount of 50 per cent. of the mercurial used occurred.

The higher the grade of hardness of the water the greater the separation of the mercurial. Fürbringer states that the addition of salicylic, hydrochloric, or acetic acid, 15 ♏ to 8 ♏ to the quart, hindered this separation, and the Munich experiments showed that the addition of 15 grains of sodium chloride to 15 grains of corrosive sublimate resulted in a permanently clear solution.

The interesting question arose, however, as to whether the addition of the salt did not result in other mercurial combinations of less antiseptic value: experiments were made upon this point, and the following conclusions reached: Solutions of sublimate alone and of sublimate with salt, each 1 to 50,000 in strength, were tested, as in weak solutions differences are most apparent.

Sterilized silk was thoroughly impregnated with anthrax bacilli, and a portion of the silk was allowed to remain ten minutes in a solution of sublimate alone, while another portion remained ten minutes in a solution of mercurial and salt: both of the solutions were 1 to 50,000. The silk was then washed with alcohol and sterilized water, and transferred to five test specimens of sterilized agar-agar. These proof-specimens were kept in a culture-oven for six days at a temperature of 36° C. without the development of bacilli.

An immersion of five minutes in the solutions resulted in the presence of bacilli in four out of five specimens placed in sublimate alone, and in three out of five placed in the mixed solution. It is evident, then, that the combination of the mercurial and the salt is equally efficient and more soluble than the mercurial alone.

Angerer has ordered made compressed tablets of sodium chloride and corrosive sublimate, eight grains of each, which he finds efficient in preparing solutions. —*Centralblatt für Chirurgie*, Feb. 12, 1887.

[The above suggests at once Sir Joseph Lister's combination of ammonium chloride and corrosive sublimate in his Sal Alembroth (MEDICAL NEWS, July 3, 1886, p. 27): the points of interest being the substitution of so obtainable a substance as sodium chloride for ammonium chloride, and the sterilizing effect of such weak solutions.]

PRESERVATION OF RUBBER APPARATUS.—An inquiry has been carried out under the direction of the French Minister of War, with the object of ascertaining the cause and the remedy for the peculiar changes which articles made of India-rubber undergo when kept in stock, the annual loss to the government from deterioration of this class of goods being very considerable. Experience shows that India rubber, after a time, loses the very qualities which made it useful, for it becomes dry and brittle. Articles kept in boxes, such as Higginson's syringes, Esmarch's bandages and drainage tubes, are particularly liable to deteriorate. Unfortunately, the commissioners, after a long and patient investigation, are not able to suggest much more than could have been recommended before. They advise, for instance, that Esmarch's bandages should be taken out of the boxes at least once a month, unrolled and manipulated. Drainage tubes should be hung up in a cool place, or soaked in a non-putrescible fluid. Finally, all objects made of rubber should be kept in a cool, damp place at a constant temperature, and sheltered from light, heat, and frost. Seeing that in many cases these conditions cannot be complied with, it is recommended that the bandages should be made of pure leaf rubber in lieu of the elastic tissue usually employed. The purer the rubber, the less readily does it undergo these structural alterations, and the lighter it weighs; its weight is, therefore, a sure guide to its quality. In consequence of these inquiries, the Minister has ordered that, in future, all rubber articles are to be made with pure rubber of the best quality, preferably with the leaf rubber. The quality of the articles will be gauged by their specific gravity in order to insure the purity of the material employed.—*American Druggist*, Feb. 1887.

PURIFICATION OF WATER BY CHEMICALS.—PROF. DOBRALSANÈNE, of St. Petersburg, recommends the following to precipitate the impurities of water:

To 12 quarts of water he adds 7½ grains of perchloride of iron, and 10½ grains of crystalline sodium carbonate; in 45 minutes the water was perfectly pure. —*Union Medicale*, January 22, 1887.

POISONING BY HERRING-ROE.—In the *France Medicale* a case is related in which a man was poisoned by eating three hard-roed herrings. The symptoms were a feeling of oppression, vomiting, burning sensation in the œsophagus and stomach, very violent abdominal pains, and dysentery. The attack lasted about forty-eight hours, and could be traced only to the herrings. Cases of this kind are by no means rare. It has long been known that caviare (sturgeon-roe) and the ova of pike, barbel, perch, and other fish, have frequently given rise to symptoms of poisoning in Russia. M. Goertz, a Russian physician, treated three cases of this kind in one family; the patients had eaten hard-roe, while the other members of the family who ate the soft-roe experienced no inconvenience. Dr. Müncheimer, of Munich, in 1875 reported three cases of poisoning after eating barbel-roe. These cases, which were very severe, were treated with ice and tincture of opium and saffron. Prof. Naunyn reported a similar case in Berlin in 1884. Among the numerous cases reported in Russia, herrings appear to have been the cause in only one. According to Huselmann, accidents of this nature, due to caviare of bad quality, are frequent and sometimes fatal among the poorer classes in Russia. It is impossible, according to him, to say exactly what the poisonous element is, and it is useless to hide one's ignorance by attributing all the effects to ptomaines. In these cases, as in poisoning by mussels, oysters, and other fish, the idiosyncrasy of the individual must be taken into account.—*British Medical Journal*, Feb. 12, 1887.

CURE OF ABDOMINAL ANEURISM BY LORETA'S METHOD.—DR. JOHN F. MORSE, of San Francisco, reports in the *Pacific Medical and Surgical Journal*, of February, 1887, a case of abdominal aneurism, whose treatment he describes as follows:

The patient, a man aged thirty-two, denied venereal infection and alcoholic excess.

On the 4th of March, 1886, he was struck violently in the abdomen by a coal bucket, which occasioned him at

the time no serious inconvenience. A week later, however, he began to suffer from vomiting and constipation which were accompanied by intense pain in the back, sides, and abdomen, and he then noticed for the first time a pulsating swelling in the abdomen. He was confined to his bed for one month, and then came under the care of Dr. Morse, who diagnosticated abdominal aneurism, and ordered treatment of rest, low diet, and large doses of potassium iodide for three weeks. At the end of this time he left the hospital much improved, and continued his work for three months: during this period the tumor had grown larger, and the pain in the back became so intense that sleep could only be obtained by the use of opiates.

On November 17, 1886, the patient was etherized, and the abdomen cleaned and disinfected. An incision four inches long was made over the tumor through the linea alba. On opening the abdominal cavity the intestines were withdrawn and covered with warm cloths. The aneurism was then exposed and found to be about the size of both fists.

An exploring needle, one millimetre in calibre, was thrust into the sac, when a stream of arterial blood spurted through it. One yard and a half of one-half millimetre silver-plated copper wire was carefully passed through the needle into the aneurism and the needle withdrawn. The slight hemorrhage resulting was readily stopped by touching the small opening with pure carbolic acid and glycerine. After the usual toilet of the abdomen, the abdominal wound was united by means of five deep and four superficial stitches. An antiseptic dressing of carbolized gauze was applied.

After the operation the patient suffered several days from vomiting, but his temperature never rose above 101° F.

The day following the operation the pulsation in both femorals was scarcely perceptible, but soon appeared again.

On the 23d of November, a week after the operation, the dressing was removed for the first time, and the abdominal wound being healed, the stitches were removed. The pulsation over the tumor was very slight.

Nothing of importance transpired until the 26th, when the patient complained of great pain in the left groin, and an examination revealed the left leg enormously swollen, œdematous, and cold, and no pulsation was to be felt in the left femoral. In the right femoral it was very feeble. The left leg was wrapped in cotton and warm bottles applied. In two or three days the swelling had disappeared, the pulsation in the left femoral not reappearing.

In another week all dressings were taken off and the patient continued to improve.

December 13. The pulsation over the aorta is no stronger than over a normal aorta, and auscultation reveals no bruit in the sac, which is extremely hard to the touch. The patient is ordered to remain quietly in bed, on his back, in order that the clot may become firmly consolidated.

17th. Pulsation over tumor scarcely perceptible, no bruit to be heard on auscultation. Patient is in excellent condition and anxious to get up. Wound in abdomen entirely healed. Pulsation in left femoral has not returned, is slight in right femoral.

28th. Patient has been up for a week. Pulsation has returned in left femoral, slightly increased pulsation over sac. Patient has no pain and is in excellent condition.

January 7, 1887. Patient is about to leave the hospital. Pulsation in tumor again diminished. Tumor reduced one-half in size at the time of operation, consists of a hard nodule. No bruit. Scarcely any difference in pulsation of femorals.

This, the first successful case of the kind, proves the feasibility of Loreta's method of treating aneurisms of the abdominal aorta.

Antifebrin.—Lépine reports his observations on the use of this drug in typhoid, in which he considers it as efficient as double its dose of antypyin. The time when the temperature will probably reach its highest point should be observed, and eight grains of antifebrin should be given an hour previous to this time. Typhoid patients apparently obtained remissions which influenced the disease favorably by this means. When the temperature fell there was no collapse; the patient felt well; the pulse-rate was slightly increased; the vigor of the heart's action was not lessened, but was often increased. In those very severely ill, cyanosis and lessening of the secretion of urine were observed.

Antifebrin, when given in severe quotidian intermittent, cured the paroxysm promptly without cyanosis. The drug is probably an antiseptic, as all antipyretics act antiseptically against certain microbes. The presence of aniline, set free from antifebrin, would account for the antiseptic action of antifebrin.

As a nervine, the drug quieted the lancinating pains of tabes in one or two doses of eight grains. The patient felt relieved after half an hour without any other apparent effect. It acted well in two cases of neuralgia; in a case of multiple sclerosis the tremors were hindered, and the strength of the patient increased.—*Centralblatt für die gesammte Therapie*, January, 1887.

Prescriptions for Menorrhagia and Metrorrhagia.—The *Revue de Thérapeutique* for February 1, 1887, gives the following for severe menorrhagia, as original with Denyau:

℞.—Aquæ dest. . . . . ʒxv.
Gummi tragacanth.,
Chloroform. pur. . . . . āā ʒj.
Tinct. cannabis indicæ . . gt. xxx.—M.
Sig.—Take in two doses.

The following are the prescriptions of Hildebrandt and Fellner for profuse metrorrhagia:

℞.—Ext. fl. hydrastis canad.,
Vini malaga,
Syrupi cinnamom. . . . āā ʒiiss.—M.
Sig.—One or two teaspoonfuls every two hours.

Berberine or hydrastine, alkaloids of hydrastis, may also be used. Fellner gives the following:

℞.—Berberin. phosphat. . . . gr. xv.
Dissolve in ʒv of boiling water.

Add:

Vini malaga,
Syrup. cinnamom. . . . āā ℥iijss.
Sig.—Twenty drops every two hours.

Also:

Hydrastin. hydrochlorat. . . . gr. xv.
Dissolve in distilled, boiling water . ℥ss.

Add

Aquæ aurantii floris,
Syrup. tolu vel syrup. menth. piper. . . ää ℥ss.

Take in the same doses as preceding.

Absorption from the Mucous Membrane of the Urinary Bladder.—The question as to the extent of absorption through the mucous membrane of the urinary bladder has often been considered both at the bedside and in the laboratory, but the results have hitherto been sufficiently discrepitant to leave room for more exact work on the subject. The latest contribution toward a solution of the problem bears the mark of exact, scientific observation, and seems to us largely to settle the matter. In the current number of the *Journal of Anatomy and Physiology* there is a paper on "Absorption from the Mucous Membrane of the Urinary Bladder," by Dr. Herbert H. Ashdown, late senior Demonstrator of Physiology in the University of Edinburgh, in which a critical summary of the work already done is given, and a series of carefully conducted experiments is reported. The observations were made on rabbits and dogs, and consisted essentially in the analysis of results obtained by the intravesical injection by the urethra of substances possessed of known physiological properties or readily estimated chemical reactions. The author divides his experiments into three groups: (1) Those in which the drugs administered have a sufficiently distinct physiological action of their own to indicate their presence when absorbed into the system; (2) those in which the renal elimination of the drugs given can be readily demonstrated; (3) those in which the quantitative analysis of a solution of known chemical composition can be conducted after it has remained for several hours in the bladder. The results of the triple series are strikingly similar, and appear to justify Dr. Ashdown's conclusions. These are: (1) That absorption of a very large series of chemical substances does take place from the mucous membrane of the urinary bladder when in a perfectly healthy condition; (2) that the urinary constituents themselves—those substances eliminated by the kidney, as effete products of the system—are absorbed from the bladder in varying productions, this applying more especially to the water and urea, but also, though to a less extent, to the inorganic solids; (3) that the degree of distention of the bladder plays a most important part in increasing or diminishing the rapidity of such absorption; (4) that regular rhythmical contractions take place in the muscular wall of the bladder; that these contractions are largely influenced by the degree of distention of the bladder, being most marked with a moderate amount of distention of the viscus, and but feebly marked in slightly distended or in over-distended conditions; and that the character of these contractions is largely affected by the nature of the fluid contained in the bladder.—*British Medical Journal*, Feb. 12, 1887.

Antipyrin in Hemicrania.—Dr. [illegible], was led, from the similarity of action between salicylate of sodium and antipyrin, to give the latter for hemicrania. From his own observations, and those of his colleagues, he was led to believe that antipyrin is more rapid and certain in its effects than the salicylate. In the beginning of the attack, and in its prodromal stage, the remedy had an abortive effect or made the paroxysms much milder than usual. Patients who were generally obliged to forego their usual occupations, and who could not sit up during the attack, were generally able to go about with comfort. When taken after the inception of the attack, and when it had developed considerable intensity, antipyrin had still a most favorable effect. Among the patients thus benefited were those who had tried all other known remedies without result. Antipyrin, however, will not relieve, in all cases, the distressing symptoms of hemicrania; there are patients with whom it has no effect, and others who are upon one occasion benefited, and who receive no relief in another trial of the remedy; the observer was not able to recognize a ground for discrimination in these cases.

In those cases in which antipyrin acted favorably a dose of fifteen grains, once administered, was generally sufficient; exceptionally, twenty-three grains were given once. Its good effects were usually manifested in one hour after taking, and when this was not the case, the first dose was repeated, and good results rarely failed. It was generally ordered in capsules or wafers. Dangerous or unpleasant effects were not observed after its use.—*Centralblatt für die gesammte Therapie.*, Jan. 1887.

Pneumotomy in Pulmonary Abscess.—Dr. Runeberg, Professor of Medicine at Helsingfors, in a clinical lecture which has been published in a Swedish journal published in Finland, gives an account of a case of pulmonary abscess consequent on acute pneumonia, where he had performed pneumotomy with success. In addition to this he had collected notes of ten other cases. Leaving aside three of the eleven on account of uncertainty in the diagnosis, five of the remaining eight recovered, or at all events improved very decidedly, and in the rest, which were fatal, death could not in any way be attributed to the operation, so that Dr. Runeberg considers that when the diagnosis of pulmonary abscess is clear, and it is in an accessible situation, the best practice is certainly to open it. He then refers to the question of operating for gangrene of the lung. He himself had had a case of this, together with bronchitis and bronchiectasis; after the operation secondary gangrene and septicæmia occurred, which proved fatal. In seventeen other cases of gangrene he quotes from medical literature where pneumotomy was performed, seven recovered more or less completely, and the fatal termination of the remaining ten did not appear to have been attributable to the surgical interference. As to the method of opening the lung, Dr. Runeberg is in favor of resecting a rib, and then using the thermo-cautery. He does not approve of washing out the cavity with antiseptic lotions, thinking them dangerous, and believing that ample drainage is sufficient. In conclusion, he mentions several pneumotomy cases he had collected: two were for ecchinococcus, both terminating favorably; six were for bronchiectasic cavities with gangrene; and six for tubercular cavities. In the latter two classes of cases he does not think operative procedures are advisable.—*Lancet*, Feb. 12, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 5, 1887.

ANTISEPTIC OBSTETRICS.

THE question of the hour in regard to obstetric practice relates to the use of antiseptics. Last year two important contributions to the subject were made in this country, one by Kucher, in his volume upon *Puerperal Convalescence and the Diseases of the Puerperal Period*, and the other by Garrigues, upon "Antiseptic Midwifery." If to these there had only been added a translation of the volume of Fritsch upon the treatment of puerperal affections, of which a French edition appeared in 1885, the American profession would have available the three most useful, brief works presenting the importance of using antiseptics in obstetric practice, and the methods of employment advised by eminent obstetricians.

The last utterance upon the subject is by RICHARDSON, in a paper entitled "The Use of Antiseptics in Obstetric Practice," published in the *Boston Medical and Surgical Journal* of January 27. Richardson states, in considering the etiology of puerperal septicæmia, that "to-day it is unquestionably admitted by many leading obstetricians that the infection must come from without." This expression of opinion, however, is not sufficiently strong, he might have distinctly said there is no such disease as autogenetic puerperal fever. Ernst, expressing the view of bacteriologists, is quoted fully in the paper as to the different varieties of bacteria which have been found in puerperal fever, the quotation concluding with the statement: "The problem is unquestionably how to keep these bacteria out of the body. Without their entrance there will be no puerperal fever or septicæmia." These are no ambiguous words, and they plainly and clearly express the truth as at present known; they remand to the region of past darkness or of only partial light the decayed doctrine of autogenesis. Here is a most useful working hypothesis furnished, and so much even the sceptics must admit, a working hypothesis which in its results has established its probable truth.

Let us see how Richardson keeps omnipresent bacteria out of the puerpera, does not allow them to come in contact with the wounded surfaces, for, as was especially emphasized by Siredey a few years ago, and as is maintained by most obstetricians today, without a wound the infectious agent cannot enter. The parturient patient is given a bath, and the genitals and surrounding parts are washed with a solution of the corrosive chloride, 1 to 3000. Thorough disinfection of the hands is made by the nurse and by the obstetrician, and when the latter makes an examination the fingers are covered with a mixture of oil of eucalyptus and vaseline; an injection of corrosive sublimate is made at the beginning of labor, and at the conclusion of the first stage and after labor is over; tears of the perineum, if requiring it, are stitched with catgut, powdered iodoform being afterward applied, and, finally, the antiseptic pad advised by Garrigues is employed.

Antiseptic injections during labor are clearly indicated, first, if the woman has been suffering from an abundant and offensive leucorrhœa; and, second, when the labor is protracted, particularly if manual or instrumental delivery be required. Otherwise, we would have only one injection used, and that immediately after labor. In this respect we prefer the practice of Fritsch to that of Richardson, and accept as ordinarily true the statement of the former as to all vaginal injections, "there is nothing hurtful in the vagina, and the detersive injections have no object." As to anointing the fingers before making a vaginal examination, it is quite probable, as taught by Fritsch, that this is unnecessary, since the fingers have been just removed from an antiseptic solution, the parts are relaxed, softened, and lubricated by the abundant secretions, and resistance and friction are absent, provided frequent injections, especially such as coagulate the albumen of the secretions, have not been made.

As to the antiseptic pad so warmly endorsed by Richardson, previously enthusiastically advocated by Garrigues, the results which each has had speak warmly in its favor. But if the external sexual organs are thoroughly cleansed twice a day by a warm antiseptic solution, and if aseptic napkins are used, the antiseptic pad may be omitted.

Antiseptic obstetrics makes sure progress, though differences of opinion may be held as to those methods which are most useful and necessary. The day surely comes, if not already here, when puer-

peral fever will no longer be thought by any an accident, and the obstetrician will be as careful to guard against septic infection as he is when he performs abdominal section. If he has failed in these precautions, and has a fatal case of puerperal fever, he can escape neither the reproach of his own conscience nor public censure.

CALOMEL AS A DIURETIC.

SEVERAL writers have recently called attention to the value of calomel in the dropsy of heart disease, and in *L'Union Médicale*, No. 12, 1887, LONGUET gives a *résumé* of the published papers. JENDRASSIK of Buda-Pesth, noted a marked diuretic effect from small doses administered to a syphilitic patient with cardiac dropsy; the diuresis was so abundant and apparently so directly a result of the mercury that he employed the remedy in a series of seven cases, and in all with decided benefit. In the first case there was a mitral lesion with œdema of the legs, Cheyne-Stokes breathing, and a very serious general condition. Digitalis and caffeine were no longer effective, and the urine had fallen to 22 oz. in the day. On the second day after the administration of the calomel there was diuresis and the amount of urine increased daily until a maximum of 297 oz. was reached, and as the dropsy disappeared the quantity gradually became normal. Three weeks later, on return of the dropsy with dyspnœa and Cheyne-Stokes respiration, the calomel was again successfully resorted to, and the patient ultimately left the hospital in good condition. From ten to fifteen grains were given daily in divided doses. The effect is not produced if the mercury acts on the bowels, and the diuresis is always preceded by symptoms pointing to the absorption of the medicine, such as the metallic taste, stomatitis, or ptyalism.

STILLER, as noted in THE MEDICAL NEWS of Feb. 5, reports equally favorable results in fourteen cases, but he gives smaller doses in the day, seven to ten grains. The diuretic action is not often evident until the third or fourth day. Opium may be added to check diarrhœa without interfering with the special effect of the mercury. He considers it a very valuable adjunct to digitalis in the treatment of heart disease.

MENDELSOHN confirms these results and gives calomel in cases in which the digitalis is inoperative, or in which it has had to be suspended for fear of its cumulative action. He gives three or four grains three times a day, and the diuresis is usually manifest within forty-eight hours, and before there are signs of absorption.

The mode of action is not very clear, but it is not due to any effect upon the heart, as the contractions are not increased in vigor, nor is the arterial tension raised. It is apparently a direct effect of the mercury on the kidneys. Longuet calls attention to the fact that Stokes recommended calomel in cases of dilatation of the heart with congestion of the lungs and liver, cardiac asthma and dropsy, and noted great diuresis with rapid disappearance of the anasarca. There is certainly clinical evidence of sufficient weight to warrant a full trial of this method at the hands of the profession.

CEPHALIC VERSION IN PRESENTATION OF THE PELVIS.

THE performance of bimanual version has been recognized as inoperative in cases of shoulder presentation. Of late, however, some obstetricians have sought to include all presentations except that of the vertex. Thus we find in the *Nouvelles Archives d'Obstétrique et de Gynécologie*, for January 25th, the report of a recent discussion in the Paris Obstetrical and Gynecological Society as to the propriety of version by external manœuvres, in case of pelvic presentation, substituting for this the head. The discussion was begun by PAJOT, and among the participants were GUÉNIOT, CHARPENTIER, DOLÉRIS, and PORAK.

Pajot believed that this operation should be proscribed, for in the cases in which it is easy it is useless, as the labor would terminate favorably without it; and in the cases in which it would be useful, notably in primiparæ, it is difficult, and sometimes impossible or dangerous. This view was sustained by Guéniot and Charpentier, but, on the other hand, Porak and Doléris gave only a qualified approval, contending that in some cases external version, by which the head had been made to replace the pelvis, had been successfully done, and that it was wise where possible to attempt this substitution, since the mortality of vertex was less than that of breech presentation.

It seemed to be generally admitted that in multiparæ the danger to the child from a pelvic was scarcely greater than from a vertex presentation, while the difficulty in performing version in the case of the primiparæ was in some cases insuperable. Among the dangers of the attempted operation, one emphasized by Pajot was, that the version might be incomplete, so that the shoulder would take the place of the pelvis, and hence peril come to the mother. Again, it was stated that rupture of the uterus, detachment of the placenta, and an unfavorable puerperium, might result from the operation. But the answer to these possible objections is that none of them has been proved, and until they are established by actual experience, they ought not to deter us from the operation.

The special variety of pelvic presentation which usually causes the most delay and difficulty in labor

is that in which the legs are extended over the chest, the body being rendered inflexible by the rigid limbs, which act as a sort of splint. In such a case the difficulty and danger in version are apparent, and we should be very loath to attempt it, especially if the child was large and the amniotic liquor scanty. Again, the breech may present in a case of narrowed pelvis, a narrowing which is not so great but that a living child may be born by the induction of premature labor; in such a case no attempt would be made to substitute the head, for whatever may be the differences of opinion as to the relative value of the forceps and version in narrowing of the inlet, the induction of premature labor limits the choice to the latter method of delivery.

The question considered by Pajot and his associates can only be settled by large and accurate statistics including cases of pelvic, and those of substituted vertex delivery, giving the fœtal and also the maternal mortality. Meantime, in the management of unchanged pelvic presentation, we should remember the wise words of Charpentier: never hurry, carefully observe the pulsations of the fœtal heart, let nature do all she can, wait if possible for the spontaneous disengagement of the pelvis and the trunk, and do not intervene until the last minute in order to assist the delivery of the arms and the head.

THE YELLOW FEVER INOCULATION INVESTIGATION.

THE Sundry Civil Appropriation Bill for the fiscal year beginning July 1, 1887, contains a clause providing that the President is authorized to use of an unexpended balance now in the Treasury "a sum not exceeding ten thousand dollars for the purpose of investigating the merits of the methods practised in Mexico and Brazil for preventing yellow fever by inoculation."

It will be seen that the President is not limited in any way as to the persons to be employed or the methods to be used in this investigation. He may detail officers from any Department of the Government service, or he may make special appointments from civil life. It is a matter of great interest to the people of the United States, and to the medical profession in particular, that the person or persons selected to make this investigation shall be thoroughly competent, and fitted by special training for the work which is to be done. In the first place, they should be men who have had yellow fever, and are therefore protected as far as possible against a second attack. In the second place, one of them at least must be thoroughly trained in the latest methods of culture and identification of microorganisms.

These two requirements point directly to Dr. Sternberg, of the Army, who is the only man in this country that we know of who possesses such a double qualification. Dr. Sternberg has had yellow fever, is thoroughly familiar with its manifestations, has already investigated it in Havana, and is well known as an accomplished bacteriologist. For these reasons in behalf of the medical profession of the country, we ask that he may be selected for this work and given the necessary assistants and materials.

A part of the investigation must necessarily consist in the careful scrutiny of the evidence that protection has been or can be conferred by such inoculations as those reported by Drs. Freire and Carmona, and this is to a certain extent independent of the question as to whether they have really succeeded in identifying the specific microörganism which produces the disease.

So far as we can now judge, they have not succeeded in doing this, and their inoculations have been made with mixtures of several kinds of bacteria, some of which at all events have the power of producing septic effects. It is, of course, possible that the true yellow fever germ may have been among those inoculated, and it is also possible that some one of the septic bacteria though not the specific cause of yellow fever, may be able to produce a condition of the system which will give immunity, or at least a partial and temporary immunity, against the fever. The investigation of the evidence as to the effects of inoculation must therefore be made whether the specific germ can be identified or not, and this part of the work will require much time, patience, and tact by a man who can speak Spanish well, and is familiar with the subject. Such a man might well be appointed, we think, from civil life, and there are several physicians in the South who possess the requisite qualifications, so that there is more liberty of choice than there is with regard to the bacteriologist. We do not see any special need for more than two persons to conduct this investigation, but the field is certainly too wide for one.

We are very glad that Congress has authorized the inquiry, and look forward with great interest to the results.

THE presidency of the collegiate department of the Long Island College Hospital, Brooklyn, has been accepted by Dr. Joseph C. Hutchison, of that city, that position having recently been made vacant in consequence of the death of Dr. W. H. Dudley, who for many years had been at the head of that institution. The new president was formerly a member of the faculty of the school, and held the chair of surgery at a time when the late Professors Austin Flint and F. H. Hamilton were also identified with the interests of the institution.

THE Pathological Society of Brooklyn was, on February 24th, addressed by Dr. H. B. Baker,

of Lansing, Mich., on the etiology of pneumonia. Dr. Baker was present by special invitation, and was greeted by a large attendance of the members. His lecture developed his views concerning the influence of weather conditions in the causation of pneumonia and other respiratory diseases, illustration by numerous diagrams being a prominent feature. After a full debate of the subject, a hearty vote of thanks was proffered to the lecturer. A resolution was also adopted expressing regret that the Michigan Board of Health appears to be in jeopardy from detrimental legislation, and asking that the said Board be amply sustained, and that funds be given it for the establishment of a biological laboratory.

As viewed from the side of the public, the removal of Major Moses Veale, the Health Officer of Philadelphia, is a most injudicious act on the part of the newly installed Governor of Pennsylvania. Major Veale has administered the affairs of his office with unusual ability, and there can be no reason why the public should be deprived of his valuable services except a compliance with the inexorable demands of the spoils system of political appointment. It is to be hoped, for the sake of the community, that his successor will prove himself capable, and will strive to maintain the efficiency which characterized the administration of the retiring officer.

PROF. LUDWIG BANDL, who was reported to have died, and whose obituary notice has appeared in a number of journals, is said to be still living. He is, however, suffering from melancholia, and his sudden retirement gave credence to the report of his death.

A NEW medical association was organized in Brooklyn, on February 25th, under the title of the Kings County Medical Association, and officers were elected for the ensuing year, as follows:

President, E. R. Squibb, M.D.; *Vice-President*, Avery Segur, M.D.; *Recording Secretary*, R. M. Wyckoff, M.D.; *Corresponding Secretary*, W. G. Russell, M.D.; *Treasurer*, J. R. Vanderveer, M.D. This Society will be in affiliation with the American Medical Association, and it proposes to give especial prominence to the cultivation of social and professional intercourse among its members.

CREMATION in New York has not progressed as rapidly as its promoters had hoped. The experience of last year shows that less than ninety incinerations were performed at the Newtown crematory, whereas the income from not less than one hundred and fifty would be required to defray the annual outlay. The stockholders of the Society owning the crematory will make good the deficiency by an assessment. The report of the Society explains that, in addition to the unpopularity of their project due to the religious scruples of various denominations, there has been encountered an unexpected obstacle in the position taken by the health authorities of New York City. The latter body have refused to issue permits for incineration on the ground that the laws of the State provide that all dead human bodies shall be disposed of by interment.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 2, 1887.

THE PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

DR. T. M. MARKOE presented a

CASE OF CIRSOID ANEURISM, TREATED BY SIMULTANEOUS LIGATURE OF BOTH OF THE EXTERNAL CAROTIDS,

with the following history: James S., aged twenty, a marine, about five years ago was struck with a club on the left side of the head near the parietal eminence. A small lump remained after the injury, which slowly increased in size, and in the course of two years became a pulsating tumor. He was admitted into the New York Hospital the last of June, 1886, and then presented a large, soft, fluctuating tumor, situated over the left parietal bone, toward which several large and tortuous branches of the temporal artery converged, and into which they manifestly opened. The same condition existed, though to a less degree, on the right side. The occipitals seemed to be but slightly involved. The pulsation was very marked in all parts of this mass of enlarged vessels, notably so in the central enlargement; a thrill was felt on placing the finger upon the vessels, and also a feeble bruit. The entire series of vessels was easily compressible. The patient had no pain, only a sense of discomfort about the head, and when he stooped or made a violent effort, he felt a distressing sense of distention. The same was true if he indulged in drink.

He was very anxious to obtain relief, as the tumor had grown so rapidly as to cover the entire left side of the scalp, and the vessels were beginning to dilate on the opposite side. It was decided to tie both of the external carotids, a procedure warmly advocated by Bruns, of Tübingen, because it seemed as if the circulation through the scalp could thus be controlled most effectually. The operation was performed on July 9th, and the dressings were not disturbed until the 27th, when it was found that the wounds had healed perfectly except at one small point, which was well in a few days. It was found at the time of the operation that the central mass consisted of a large ampulla, with which several dilated arteries communicated. The pulsation ceased after the operation and the dilated vessels gradually disappeared; but the ampulla still remains, although it no longer pulsates. Although the cure in this case is not perfect, ligation of the carotids seems to give the best results. Extirpation of the tumor is another alternative,

but it is limited to cases in which the mass is circumscribed. It is sometimes successful, but often fatal.

In reply to a question from Dr. Wyeth, he said that the carotids were tied below the lingual arteries so as to control the circulation through the occipitals. There were very few cases in which any operation had been perfectly successful, except those in which extirpation could be accomplished. He recalled an instance in which the late Professor Van Buren had tied in succession every artery that entered the tumor without producing any visible effect upon it. If employed in any early stage of the disease this operation of ligature of both external carotids promises much.

Dr. Wyeth said that this was the first case that he had seen in which both carotids were tied to cure cirsoid aneurism. Up to within twelve years the external carotid had only been tied about sixty-seven times, but since then the operation has been performed very often, and there has been, so far as he has noticed in the journals, no dangerous secondary hemorrhage in any instance where animal ligatures had been used. The speaker said that he had tied the external carotid five times below the origin of the lingual (on both sides in one instance), and even at the very point of bifurcation.

Dr. Stimson said that there still seemed to be marked pulsation in the vessels; might it not increase?

Dr. Markoe replied that the pulsation was certainly diminishing; it was possible now, he added, either to inject some coagulating fluid, or to excise the entire mass, if it seemed desirable.

Dr. Stimson remarked that in the successful cases which had been reported, the central cavity itself was destroyed; tying the arteries is only a preliminary step in the operation, which alone is rarely sufficient to effect a complete cure.

The President doubted if it was possible to effect a radical cure of cirsoid aneurisms without encircling the entire tumor. He had produced some benefit by tying the main artery, but the pulsation eventually returned. His last case was one of large pulsating orbital tumor, to cure which he ligated the common carotid artery, when the pulsation nearly disappeared, but gradually recurred. He then dissected out the tumor entire; fifty vessels requiring ligature in spite of the fact that the main artery had previously been tied. When the patient was last seen the pulsation had stopped.

Dr. Wyeth referred to a case of Mussey's, in which he tied both common carotids, and was even then obliged to dissect out the tumor.

ABSCESS OF THE HEAD OF THE TIBIA; RESECTION OF THE KNEE.

Dr. Poore presented a girl, eleven years of age, who had always had some trouble in her knee. About eighteen months before, it became flexed and ankylosed. Last October he excised the joint, and found an abscess in the head of the tibia above the epiphyseal cartilage; this was thoroughly scraped out and drained. The patient recovered rapidly, the wound healing under two dressings. There was slight motion; about one inch shortening. The patella was removed.

In reply to a question from Dr. Markoe, he said that he had never seen cases in which the ligamentous union yielded after a time. After scraping out the abscess-cavity he introduced a drainage tube through the bone. He had drained several joints in this way, and believed that a good deal of bone was thus saved.

Dr. Lange announced that a patient upon whom he had performed the

NEW OPERATION FOR PROLAPSUS ANI,

was unable to be present. He presented a patient from whom he had removed a

SARCOMA OF THE RECTUM

by drawing down the gut and excising it. He had attempted to form a constriction by uniting the muscles in the manner described at the former meeting. The patient had perfect control over her sphincter when her bowels were somewhat constipated, but not when they were loose. She was obliged to wear a napkin, but seldom soiled it.

Dr. Stimson examined the patient at Dr. Lange's request, and stated that he found an orifice admitting the index-finger as far as the second joint; beyond this point there was a firm, cicatricial mass, which it was impossible to pass. When the patient was told to contract her muscles, the contraction of the levatores ani could readily be felt.

Dr. Weir then read a paper entitled

FOUR MONTHS' OPERATIVE WORK AT THE NEW YORK HOSPITAL,

of which the following is an abstract; sundry cases having been of necessity omitted.

From October 7, 1886, to the present time, he has had in his ward 339 patients of all kinds, and 105 operations, a large number of which were of importance. Of these there were 19 done on the head and neck, 53 on the trunk, of which 23 were in the genito-urinary apparatus, and 33 on the extremities. This is a division, which, while not strictly scientific, allows of ready grouping of cases, and on this account is adopted.

The *operations on the head and neck* were principally the following: Two for the relief of *deformity of the nose*. The points of each are worth a brief mention.

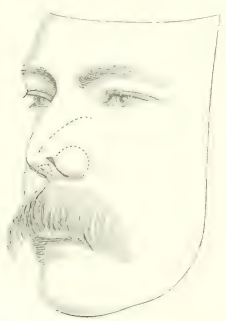
INJURIES OF THE NOSE.

C. F. P., aged nineteen, was admitted January 4, 1887, with the statement that fifteen years previously he fell a distance of seven feet, striking his nose, flattening it by apparently crushing in the cartilaginous septum. The nose is now increased in breadth at the lower part and sunken in, and the nasal process of the maxillary bone is unduly prominent. The septum is much thickened for half an inch below the skin, but not deviated. On January 7th, with a fine wood-engraver's chisel, Dr. Weir cut through from without the superior maxillary processes, and forced them inward and toward each other, and held them *in situ* by a needle passed transversely across the nose, the ends of which were prevented from pressing against the skin by pads of iodoform gauze. At the tip of the nose, from within the nares, the thick skin was separated for a considerable distance upward by subcutaneous dissection from the cartilage, and pulled forward, and held by a silver wire clamped at each end with a shot over a little cork plate, so that the broad, flattened under surface of the skin could be brought together.

The upper pin was removed on the fourth day, as some sloughing from pressure was apprehended; this immedi-

ately ceased. The lower wire was kept in for twenty-four hours longer; no ulceration had taken place under the cork pads. Lateral compresses were kept on for a few days longer. The result was excellent and the patient was submitted for inspection.

The second case consisted in replacing the parts lost by the end of the nose being bitten off in a fight. A portion of the tip and of the ala had been removed so that the nostril was carried upward. This is best shown in the accompanying illustration, in which the



outlines of the flaps made for closing the defect are also seen. The curved flap of skin was severed from its attachments up to just below the inner angle of the eye and drawn downward and fastened by black silk sutures, and the ala separated except at its lower portion and tilted forward and downward. The result was fully satisfactory, though the utilization of a portion of the columna to fill up a slight gap in the edge of the nostril was subsequently necessary.

Beside these external nasal operations, there were two others of more importance, one being

A PECULIAR BONY TUMOR OF THE NOSE,

met with in a young woman of twenty-two, who had had since her tenth year difficulty in breathing through the right nostril. This had lately increased and had been associated with hemicrania of that side. At the orifice of the nostril was seen a fleshy mass which covered a bony resistant mass. Nothing could be passed alongside it. Although no swelling of the cheek existed, it was determined at the operation, after the exposure of the bone by the usual incision from the middle of the lip around the nose, to open the antrum to see if the growth invaded that cavity. This was done with a small gouge; it proved to be free from disease. The bony growth, which apparently consisted of a greatly developed inferior turbinated bone, was removed with forceps, and the operation supposed completed; but it was noticed that the blood collecting in the nose did not run down the throat, and this was found to be due to the posterior portion of the bone shutting off the posterior nares and permitting only a fine probe to be carried into the naso-pharynx. This part of the bone was thereupon removed, when the passage was found to be quite clear. The patient has since been free from all unpleasant symptoms, except from the annoyance of a collection of muco-purulent crusts.

AN INTRABUCCAL DIVISION OF THE INFERIOR MAXILLARY NERVE

was done for a severe neuralgia affecting the right side of the face, but principally the lower teeth, with flashes of pain along the course of the auriculo-temporal nerve. An incision in the mouth was made from the upper to the lower jaw, along the inner edge of the latter. The spine of Spix was exposed, and after being seized with slender but strong forceps just before it enters the dental canal, the nerve was divided by scissors above and below the bite of the forceps. The little scrap removed, however, did not plainly show nerve tissue, so, after several endeavors, a short-curved blunt hook was introduced two or three times, until finally it was passed well back and drawn forward, with a seizure of what was supposed to be nerve. This was divided with scissors, when quite a severe hemorrhage took place, only controlled by rapidly packing the wound with iodoform gauze. The hemorrhage recurred the same evening to the extent of several ounces more, and was checked by a further compress and by binding the jaws tightly together, which forced the compress more firmly against the wound. The gauze was removed piecemeal from the wound, the last being taken away by the tenth day. The patient has been, when last heard from, four months from the time of the operation, entirely free from pain and has gained greatly in flesh.

Whether the hemorrhage came from the inferior dental, as he feared at first, or from the internal maxillary, he could not positively determine, but as he had heard of a similar mishap in an operation much more simply conducted than this, he had been led to think it was from the former vessel. He has performed the operation now three times. In the first case it was readily completed with the removal of a small portion in the grasp of the slender forceps used, and the success was permanent. In the second a good deal of difficulty was met with, until the nerve was finally divided; pain recurred after three months interval.

Of the surgery of the brain, two interesting examples can be given; the first of which is one of

CEREBRAL ABSCESS FOLLOWING AN OLD INJURY.

Patient received an injury of the left frontal region just above the eyebrow, in 1880, by his gun exploding and lodging its breech-pin in his brain. When extracted, at this hospital, the anterior clinoid process of that side could be felt by the finger. A number of bone fragments were removed with some brain substance. No cerebral symptoms followed until four months later, when infrequent epileptic fits showed themselves, but none have occurred during the last two years. He had, last summer, a painful pulsating swelling over the site of the old injury, which passed away under large doses of iodide of potassium and by local blistering. About ten days ago he began to have much pain and headache on the left side of the head over the brow. When sent to the hospital by Dr. Seguin, November 7, 1886, there

was some œdema of the left upper lid and great sensitiveness over the region of the old cicatrix, and a sense of deep fluctuation was also to be felt; no paralysis of motion or sensation. A V-shaped incision, raising the old scar, was made under ether until an opening in the skull the size of the thumb nail was reached; this was filled with a dense membrane which visibly pulsated. A puncture with a hypodermatic needle revealed pus, and the membrane was accordingly incised and nearly two teaspoonfuls of pus evacuated. The cavity of this abscess reached nearly an inch beyond the skull level. It was at first thought that it might be the original frontal sinus, but its depth and the plainly seen pulsation showed it to be the cranial cavity, though shut off from the brain by a thick layer of old inflammatory material. It was dressed from the bottom with iodoform gauze. During the evacuation of the pus respiration wholly ceased, and only by artificial respiration, lowered head, and whiskey hypodermatically, could it be started again. It was a query whether this was due to the ether or brain interference, or both. This has been noticed by others in abscess of the brain. (See Nancrede, *American Surgical Association Reports*, vol. ii.)

The second case was an unsuccessful attempt at

REMOVAL OF A SARCOMATOUS TUMOR FROM THE BRAIN.

Spurred by the brilliant though unsuccessful result of operative interference in cranial growths by Godlee, in 1884 (*Lancet*, 1884, vol. ii. p. 1090; 1885, vol. i. p. 13), which had been followed by a case reported by Hirschfelder and Morse (*Pacific Medical and Surgical Journal*, April, 1886, p. 210), and by a third and fourth one by Horsley ("Brain Surgery," *British Medical Journal*, October 9, 1886. Four cases given, two for tumor. Results satisfactory), whose paper, rich in suggestions, was received too late to be of use in the case to be immediately given, surgeons will undoubtedly be led to widen their domain, and exploratory operations in this region of the body will soon become numerous. The history of an unsuccessful case will, however, serve an important purpose, and it is now intentionally brought forward to illustrate strongly the difficulties that surround the subject, not only to the surgeon but to the neurologist who guides the knife.

Mary R., aged twenty-six, was admitted into the hospital, September 16, 1886, with the following history. Has had four operations in this hospital for sarcoma of the neck, the first two years, the last six months ago. In this last operation the left brachial plexus was freely exposed and patient afterward suffered from paralysis of the left upper extremity, from which she has only partially recovered. For two months or more she has been annoyed by precipitate micturition and defecation. Six weeks ago she first noticed cramps in the calf of the left leg which usually occurred at night and prevented her straightening it. At about the same time she noticed that the left knee frequently gave way under her while she was standing, and once or more she fell from this sudden giving way of the left leg. During the last week she has noticed occasional clonic spasms in the left lower extremity. During the past six weeks she has had frequent cramped feelings in the left hand and also numbness, and in last two weeks has had cramps and numbness in the *right* hand. For the past three weeks she has suffered intensely from frontal headache, generally on the right side, and always worse on walking. Besides this she often feels as if her head were being hammered.

Examination.—No tenderness on any part of scalp or over either supraorbital nerve. No paresis of any muscle supplied by a cranial nerve. Right hand perhaps a trifle weak, but the old paralysis of the left hand prevents any comparative test. She has paralysis of the left sympathetic as shown by narrowing of left palpebral fissure (from sinking of the eyeball) and contraction of pupil. Left biceps, triceps, and deltoid are paralyzed, and there is paresis of left lower extremity below the knee. Left patella reflex exaggerated. Ophthalmoscopic examination shows slight left optic neuritis, the outline of optic disk at exit of large bloodvessels being indistinct.

The paralysis of the left leg slowly deepened, though she would at times have twitching of the right side; and while waiting further developments she, on Oct. 11, became rapidly stupid, and on consultation with Dr. Amidon, who had had the case under observation prior to her coming in the hospital, an operation was advised and performed under his directions.

Operation.—The fissure of Rolando being previously marked out and the tumor located at upper limit of this line one inch from median line by Dr. Amidon, who had kindly seen the patient and advised the operation (scalp being shaved at this point), a crucial incision was made with long limb of cross just in front of and parallel with fissure. Scalp dissected up and with large trephine a button of bone removed from a spot one and a half inches to right of median line. This opening was enlarged by double gouge forceps to a size one and a half by one inch. Dura mater was found to be very tense and bulging. A crucial incision was made through this membrane, whereupon the deeply congested brain substance protruded into the wound. Nothing was felt by the finger, and a needle carried in several directions to varying depths failed to encounter resistance. As the brain projected beyond the skull level, a piece of it as large as half a hen's egg was cut off, and reserved for microscopical examination. Its substance was deeply pigmented and very vascular. Bleeding was quite profuse, and was checked by pressure and Paquelin's cautery lightly applied. The flaps of dura mater were laid over the divided brain and a strip of iodoform gauze over this, one end of which was carried out the posterior angle of the wound. The scalp was sutured closely up to this point and bichloride gauze dressings applied. The iodoform gauze was drawn out forty-eight hours later. Prompt healing of wound occurred, but within six days bulging took place through the cranial opening under the healed scalp and gradually increased till the hernia was the size of a hen's egg.

No unfavorable reaction followed the operation. The following signs of improvement were observed and put down to the lessened brain tension; viz., the headache, which disappeared immediately and did not recur. The spasms of both limbs also ceased, and a temporary improvement in the damaged muscular power of the left side was observed. The character of the removed piece suggested from a gross appearance the possibility that it might be infiltrated with soft sarcomatous growth, but the microscope showed nothing abnormal. In about three weeks after the operation decided signs of

right-sided analgesia and paresis showed themselves more plainly and the same deepened on the left side. It was evident that the neoplasm, or a second one, was situated at the upper portion of the cord or in or near the medulla. The patient gradually became more paralyzed and died December 25th, nearly two and a half months after the operation. The report of the autopsy as made by Drs. Amidon and Vought is appended, with the description, by Dr. Peabody, of the tumor found.

Autopsy.—The hernia cerebri so prominent during life was entirely collapsed. On removing the scalp it was necessary to split some connective tissue growth between scalp proper and the more intimate covering of the hernia. There were slight adhesions around the trephine opening between the dura and pia. On removal of the calvarium considerable apparently disorganized cerebral substance bulged from site of operation. Bloodvessels of pia and pia itself all over the brain normal.

On transverse section through both hemispheres nothing pathological was found except a slight diffuse hardening (probably inflammation) in the centrum ovale underlying the site of operation.

The cerebral ventricles were normal. On examining the base of the brain there was seen a grayish, translucent tumor springing from the under surface of the left lobe of the cerebellum, exerting much pressure on the underlying medulla, which was much crowded to the right and forward. The pressure was exerted on the medulla below the calamus. Medulla at this point much flattened. On dissection the nervous substance of the medulla proved to be entirely uninvaded by the growth, while the connection with the cerebellum was extremely intimate. An incision through the antrum of the left cerebellar lobe showed no diffuse infiltration of that body. The fourth ventricle was invaded by the growth, although apparently removed from pressure by the same. Starting from the cerebellum as described, the growth extended down the left lateral posterior region of the spinal canal, within the dura and apparently outside the pia for a distance of at least ten centimetres, the cord, of course, being crowded much to the right and forward.

Tumor grayish, translucent, and apparently non-vascular and non-inflammatory throughout.

Short segments of three spinal nerves were removed from the left side of neck, probably the fourth, fifth, and sixth. They were found to be normal.

Small subcutaneous tumor (fibrous) taken from back, little below right scapula.

Tumor of cerebellum and cord, on section, proved to be an ordinary spindle-celled sarcoma with many round cells. It was not very vascular, and the stroma was not abundant. Tumor had no connection with cerebellum, it having apparently originated in the pia.

An additional case of supposed tumor in the cerebellum, now in the ward, points out the diagnostic difficulty of such cases, as the examination of four distinguished neurologists assigned different cerebral localities to the growth.

On this, and all points, in fact, connected with this subject, the admirable collection of 100 cases of cerebral tumors with their analysis, by Dr. W. Hale White, lately published in *Guy's Hospital Reports* (vol. xxv, series 3, 1885–1886), will be of great service to the investigator. Of the tubercular tumors, 45 in number, more than half of them occurred in children under ten, and when in adults they usually had tubercular disease elsewhere; like the carcinomatous tumors, 5 in number and all multiple and secondary, these are unfit for surgical interference. Out of the 24 gliomata and 10 sarcomata (cysts being only 4 in number and too rare for consideration), which alone offer a reason for surgical interference, there were only 4 cases that could have been removed with any certainty, and 2 of these were in the cerebellum, and were gliomata. Only 1 of the 10 sarcomata was removable. Aside from the situation often precluding the operation, the frequent occurrence of infiltration of a sarcomatous growth will have the same effect. This existed in the case reported by Hirschfelder, where only a portion of the neoplasm could be taken away, the patient dying from suppurative encephalitis eight days later. White's other cases were: gummy tumors, 5; gliosarcoma, 2; lymphoma, 1; myxoma, 1; doubtful, 3.

Taking into consideration the question whether these tumors could be, during life, localized sufficiently to warrant surgical attack, White found that, from this clinical standpoint, 3 tubercular tumors might have been removed, and that 4 gliomata, 1 sarcoma, 2 cysts, 1 myxoma, and 2 of the 3 doubtful cases, or, in other words, about ten per cent of his collection, might have been operated on, *provided* that a correct diagnosis could have been made, a condition which is sadly nullified by his just statement that the best diagnosticians so frequently make mistakes that a certain number of cases suitable for operation might be failures because the position of the growth will not be exactly made out. For further inquiries concerning this interesting though somewhat obscure and difficult subject, reference should be made to this article *in extenso*.

For the special points in the operative technique, the best that has been given yet is by Horsley, briefly summed up as follows: In addition to the strict antisepsis, he makes, after an oval scalp wound, a very large cranial opening, using trephines two inches in diameter, and replacing the bone when possible; the dura mater is cut nearly round, and turned back like a large flap, and in incising the brain the cuts should be vertical and directed into the corona radiata to avoid damage. Hemorrhage should be checked by pressure; drainage of the wound is also urged.

Stress is laid by him on the immediate bulging out of the brain as indicative of a tumor; it was present in all three of his cases and in my own, but is not met with, he says, in healthy animals on whom he has experimentally tested this. This is, therefore, a symptom of intracranial pressure of high importance.

Of the operations on the neck there was a rather pleasing outcome of an intractable affection shown in a case in which a novelty was resorted to in the

EXTIRPATION OF A SUBHYOID BURSA,

which had existed for fifteen years, in a man of twenty-two, and which had attained the size of a small egg. It had been tapped and injected with tr. iodine four months previously at another hospital. Appreciating the difficulty of dissecting out satisfactorily these troublesome thin-walled cysts, he emptied it with a

trocar canula and injected into it melted paraffine (which liquefies at a point much below 212°), and subsequently cooled it with a small bag of ice. The whole procedure did not occupy five minutes, and by its aid Dr. Weir was enabled with great ease, after exposing it by section through the skin and thyro-hyoid muscle, to remove the entire sac, even up to its attachment at the posterior border of the hyoid bone, which part would undoubtedly have escaped his dissection had the cyst been left flaccid instead of being rendered a hard and tense mass. This method has in other instances served him well, and is to be commended as avoiding the persistence of the fistula which so often results from this bursal inflammation.

In

MAMMARY AMPUTATIONS FOR CANCER

the custom is adhered to of removing not only the entire gland, but also all the axillary contents, even though no enlarged glands are to be felt through the skin or even after the axilla is opened. In doing this the directions first given by Bickersteth, of Liverpool, have been followed by carrying the incision well onto the arm on a level with the insertion of the pectoralis major, and then tearing or cutting through the thin layer of fascia there present, when, with the aid of blunt scissors or the finger-nail, the axillary vein can be isolated in nearly its whole extent, especially if a broad retractor holds up the pectoral muscle. If it cannot be so exposed, and the need exists by reason of glandular growths, the muscles and the pectoralis minor are without hesitation divided. After the vein has been duly cleared, the fatty mass in the axilla is easily peeled away from the chest wall, any veins of size being tied before being divided. The cavity thus made occasionally needs from its extension toward the scapular angles to have the drainage opening for the axilla made well below the line of the incision.

More important, because less known, is the fact that there is frequenty found, beside the infected glands near the axillary vein, an enlargement of a lymph vessel with several minute glands, which run under the pectoralis minor in a line toward the sterno-clavicular articulation. He had so often found them since his attention was accidentally called, a few years since, to their presence, that he never failed to hunt for them, and many times to find them.

HERNIA

Six cases of hernia, two strangulated hernia, two irreducible, and two reducible, but all inguinal, were treated by the radical operation of tying off the sac and sewing up the ring by Czerny's method in one case, and in five others by tucking up the sac and sewing up the canal and ring, as has been suggested by Macewen. This latter operation has been simplified (see a paper on "Reducible and Irreducible Hernia," by R. F. Weir, read before the State Medical Society Feb. 3, 1887, *Medical Record*, March 5, 1887) by exposing the external abdominal ring and then pulling apart the tissues over the sac with forceps until the latter is reached, when it can be readily lifted out of its bed with much less disturbance and more certainty than if reached first lower down. Less chance of suppuration also occurs from the slight cellular disturbance thus made. In one case a concealed atrophied testicle was removed, and in another case of congenital hernia the sac was cut off and a roof thus made to the tunica vaginalis. Whenever omentum is found in a hernia, whether reducible or irreducible, it is carefully tied with multiple and a final encircling silk ligature. Where omental adhesions plugging the internal ring are met with, they are detached with the finger so as to allow the omental stump to drop back into the abdominal cavity.

His individual preference, from a necessarily small experience with it, is for Macewen's operation, as it accomplishes better not only the closure of the peritoneal funnel at the internal ring, but also effects more positively the sealing or narrowing of the inguinal canal. The success of the radical operation as determined by large figures, is about sixty per cent., and from the interannular injection of Heaton, of which one case is reported, about thirty per cent. of cures can be expected in inguinal herniæ of small size and with a yet existing oblique canal. Chromicized catgut is used in the radical operation for sewing up the canal and ring in preference to silk or wire—and among the list is a case where eight months afterward a silk ligature caused an abscess and fecal fistula, which latter promptly closed after the withdrawal of the offending foreign material. He has practised for over two years the healing of the wound by granulation, at least that part of it immediately over the external abdominal ring, as this affords, to his mind, an additional barrier to the relapse of the hernia.

On and about the rectum ten operations have been performed. Three for ischio-rectal abscesses of unusual size, which accounts for their being carried in a report where abscesses and minor operations have been omitted, save where some point of interest could be elicited. Such an instance is present in the four cases of

FISTULA IN ANO

that were divided in the ordinary way. He had had eight cases in which this affection was treated by Jenks's ("New Method of Operating for Fistula in Ano," *Trans. Am. Gynecolog. Soc.*, p. 136, 1883) method of cutting out the fistula and sewing up the fresh surfaces from the bowel to the original skin opening. In three of these eight, the fistulas were not deep and were of moderate extent, and they did well; in the others, five in number, the fistulas had a deep internal orifice, their tracts were either larger or deeper, and in two cases had diverticula, so that the dissection of the suppurating canal itself was difficult, and also the final suturing, particularly in respect to the closure of the bowel end of the incision. And after all this had been done, failure was met with in four out of the five cases. As the last trial was as unfortunate as the first, he could not lay it all to inexperience in the operation, and hence his faith in the method had much lessened.

In the four cases of

HEMORRHOIDS

he had likewise returned to the so-called method of Allingham—after a trial in five cases with Whitehead's ("New Method of Treating Hemorrhoids," *Brit. Med. Journ.*, Feb. 4, 1882) plan of cutting off the pile, tying the main vessels and then sewing together the divided mucous membranes. There was in nearly every one of these cases so much troublesome oozing from the small veins of the divided tissues, which had been cut as in

Allingham's operation, that the little operation was rendered unduly prolonged and annoying, and the result did not show any rapidity in the cure, nor any diminution in the after-pain and other discomfort often encountered in operations for hemorrhoids. He had also, in six cases, tried crushing off the pile after partial section, as has been practised by Mr. Allingham with a fairly satisfactory result, but has had at all times the feeling that the patient would be safer from the risk of hemorrhage with a tied vessel, and not enough advantage has accrued so far to warrant him in incurring further this possible danger.

Two cases of

STRICTURE OF THE RECTUM

have been operated upon.

One case was in a woman, and the stricture, a moderately ulcerated and rather narrow fibrous one, admitting only the little finger, and apparently due to parturient causes, was situated about one and a half to two inches from the anus. Instead of resorting to Verneuil's proctotomy, or its modification by the use of the knife in lieu of the galvanic or wire écrasuer, he put into service a plan which he has now used four times in the last three or four years with excellent results. He had found in practising eight times the free posterior incision of the rectal stricture with its conjoined incision reaching back to the coccyx, that the subsequent healing of the external wound was very tedious, frequently occupying more than a year, and was also associated with more or less loss of sphincter power. So, as before stated, he has changed this cut, particularly in strictures situated within two and a half inches from the anus, to one made posteriorly to the coccyx or sacrum, after stretching the anus, without dividing the external sphincter. To avoid the collection and retention of secretion in this wound pouch, a puncture with a knife is made from the point of the coccyx to the wound in the bowel, and through this is carried a drainage tube. In other words, a traumatic fistula in ano is made. The wound in the bowel is then packed with iodoform sticky gauze, and an antiseptic dressing applied over the anus. The bowels are kept quiet for several days, and if the temperature shows that all is going well, the drainage tube is withdrawn on the third or fourth day. In every one of the instances in which this plan has been tried the tube opening has promptly closed up, so that no fear of a permanent establishment of a fistula need, he thinks, be entertained. The use of a large bulbous or rubber bougie, is subsequently kept up at regular intervals, according to one's judgment.

The result as to relapse by this plan have been, as to the stricture, equally satisfactory with the major operation, and more so as to rapidity of cure. For higher strictures, the open method is wiser, as it admits of the knowledge and repair of every damage that may be possibly done to the peritoneum.

One case of

SPINA BIFIDA

was treated by injection in a child, eight months old, in whom the tumor, the size of a large orange, was situated on the upper part of the sacrum. Cutaneous outgrowths rose up on its base nearly to its vertex, where they were lost in a thin, pellucid cyst-wall. Puncture had been tried some weeks previously, with aggravation of the existing paralysis of the legs. The child was in robust health. After withdrawing, by a needle thrust through the adjacent sound skin into the tumor, about one drachm of a clear, colorless fluid (which was subsequently found to be sugarless), a similar quantity of Morton's fluid was slowly thrown in. This fluid consists of 10 grs. of iodine, with 30 grs. of iodide of potassium, dissolved in ℥j of glycerine. No special reaction followed its use, but the swelling a month later was decidedly less in size, though it is probable that a repetition of the injection will be necessary. In the *Transactions of the Clinical Society* for 1884 and 1885, 50 cases are given of this treatment, with 41 successes, as opposed to the use of the simple tincture of iodine, of 20 cases and 5 deaths.

In the genito-urinary subdivision of the operations on the trunk there have been 24 cases. Among these there is one of

VARICOCELE

treated by a method (*Medical Record*, March 20, 1886) which he had elsewhere seen suggested, and which was as suitable for those of large size—that is, by ablation of the scrotum, and the subsequent ligation of the exposed and easily attacked veins, care being taken to leave untied the packet of veins accompanying the vas deferens.

Beside this, two cases of

DOUBLE HYDROCELE

were treated by Volkmann's method, as they were considered too large to be remedied by the carbolic acid injection of Levis, which is yet considered the best treatment for hydroceles of ordinary size, or even of large size, if a preliminary tapping be resorted to, to diminish them.

In all the

URETHRAL OPERATIONS

it is the custom to smear the hair of the pubis and perineum with iodoformed oil, gr. iv ad ℥ij of fluid cosmoline, and to inject a small syringeful of the same into the urethra before any instrument is introduced into the canal. All these latter are greased with iodoformed vaseline, ℥j ad ℥j (which keeps freer from chemical change than does the oil).

URETHROTOMY.

For the division of deep and even tight anterior strictures reliance is placed on Maisonneuve's urethrotome, whose blade cutting upward he has had enlarged to one of 11 mm. in breadth, but even with this a cut made in the usual manner can enlarge the canal only to about the size of a No. 26 French sound, but by twisting the handle of the cutting blade as it comes forward from beyond the already divided stricture a second cut may be made in the roof of the urethra. By this means enlargement to 32 or 34 of the French scale, and sometimes more, can be obtained. If any anterior obstructions of large size are met with, they are cleared away by Otis's urethrotome. After all the cutting has been done, including the division of the meatus urinarius, the urine is drawn, and the bladder washed out several times with a 1 to 10,000 bichloride solution, and the urethra is also flushed generously with the same solution as the catheter is withdrawn. The penis, if any anterior coarctations have been divided, is snugly bandaged, and the

patient given, two or three times for the first twenty-four hours, ½ gr. morphine, with 3 to 5 m. tr. aconit. rad. No instrument is passed until four to seven days have elapsed, and not then if any temperature elevation should exist. By this means urethral fever has practically been abolished, and, for this reason, the plan of action has been detailed at this length. Before leaving the hospital, every patient is provided with a proper sound, and taught to use it.

External urethrotomy was done in a case of recently received

RUPTURE OF THE URETHRA

from falling astride a step-ladder, cutting into a mass of extravasated blood, in which the ends of the membranous urethra were found to be torn across and jagged. The proximal end of the urethra was more clearly made out by the prolonged use of a douche of hot water, which stopped the oozing of fresh blood, and also washed away the obscuring clots, etc., and left the urethra to stand out white and sharply defined. This expedient has proved of service in several other cases in which difficulty till then had existed in distinguishing the position of the urethra. The prompt employment of incision for a ruptured urethra is still recognized as one of the decided modern improvements in surgery. The patient did well.

Of more interest was a case of

SUPRAPUBIC CYSTOTOMY FOR SUPPOSED TUMOR,

which operation was done in a man of twenty-four, who had been passing bloody urine for six months previously with moderate pain and increased frequency. No enlargement of prostate or renal tenderness detected. A searcher in the bladder failed to touch a calculus. No renal elements were found on microscopically examining the urine, nor was any portion of a tumor cast off, though repeated search was made among the many small clots passed. The pain in the bladder on sudden motion became more marked and he was, early in December last, placed under ether and the bladder thoroughly examined by the bimanual method, also by sound and by lithotrite, and also by Bigelow's aspirator. No calculus was found nor evidence of tumor obtained. One mass removed showed a small collection of shapeless epithelial cells, but no stroma. It was decided to explore the bladder by the suprapubic cut. This was done December 23d, after the rectum had been distended with a bag holding eight ounces of water (see remarks on this point in THE MEDICAL NEWS, of December 4, 1886), and then the bladder filled with first six and a half ounces of 1 : 100 carbolic acid solution; but as no distinct elevation of the bladder above the pubes could be felt, a further three and a half ounces were slowly introduced, when the top of the bladder was lifted one and a half inches above the bone. The bladder was reached by the usual incision and opened with but little hemorrhage. The exploring finger did not feel any calculus or any tumor, as was expected. Inspection of the bladder was rendered difficult by the great rigidity of the strongly developed recti muscles, acting as they did more than usual, owing to the difficulty in maintaining perfect ether anæsthesia. By blunt retractors introduced into the bladder wound and by raising the heels of the patient over an attendant's shoulders, as suggested by Trendelenburg, Dr. Weir was enabled to secure, with the additional aid of a small portable electric light, a very good view of the bladder: only an intensely congested and easily bleeding mucous membrane was seen. No attempt was made to sew up the wound, which was packed lightly with sticky iodoform gauze after a drainage tube had been inserted, and the patient kept turned on alternate sides for three days, when the tube was also removed.

No reaction followed the operation, but the bloody urine continued to be passed, and two weeks later, the wound still admitting a finger, the patient was again etherized with the idea of isolating the mouth of the ureters and thus ascertain whether the hemorrhage came from the kidneys. This was soon proved to be a difficult affair; the use of various endoscopic tubes and mirrors and even a long but narrow glass speculum was inefficacious in obtaining the desired view, and the insertion and dilatation of Peterson's rectal bag with seven and a half ounces of water, while it brought the base of the bladder one inch nearer the surface and closer to the pubis, did not serve to permit the recognition of the orifices of the ureters. The hindrance was, as before, mainly due to the difficulty of overcoming by ether the strong resistance of the well-developed recti muscles. It was, however, seen that the lower part of the bladder was studded over with a number of elevations the size of hempseed, which bled freely when rubbed by an instrument. Three weeks later the suprapubic opening closed, and patient's urine is becoming less and less bloody, but the solution of the case cannot yet be fairly claimed to have been made. He still remains under observation.

(To be concluded)

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, February 3, 1887.

THE PRESIDENT, THOMAS M. DRYSDALE, M.D., IN THE CHAIR.

DR. H. A. KELLY called the attention of the Society to an external direct method of

MEASURING THE CONJUGATA VERA,

which he had found of extreme value in a large number of non-pregnant gynecological cases which had come to him complaining of difficulties since a previous confinement.

A short vagina, or cellulitis, or cicatricial contractions, often prevent the finger in the vagina from reaching the promontory. In a case he had examined in the morning, the short vagina prevented the vaginal finger reaching the promontory while the outside hand rested upon it, and on pressing deeper felt the vaginal fingers fully three centimetres below. This case was measured by the outside hand and determined normal. Another case had a rachitic pelvis 8½ cm. conjugate. She had borne ten children at term through difficult labors, but without assistance.

The method is simple, avoids a vaginal examination in the virgin, is invaluable in many cases retrospectively and prognostically. The inaccuracy of the external conjugate is well known. This, of course, is of no

use in the most important class of cases, the advanced pregnant, but it does often afford invaluable facts in other cases.

The method is to press deeply with the finger tips of the extended hand until the promontory of the sacrum is felt, then by slipping the fingers up and down over this until the relations are well appreciated, let the fingers rest vertically above the angle and at the same time mark on the palm with the finger of the other hand the position of the posterior surface of the symphysis, also vertically below. This measurement from the mark thus made to the tip of the finger is the conjugata vera thus directly measured.

Dr. Montgomery, in a paper entitled

TRACHEOTOMY AND INTUBATION IN DIPHTHERIA,

urged the importance of early operation. The symptom which should indicate the necessity for operation was depression of the substernal region during inspiration. This symptom indicates the inefficient entrance of air to fill the lungs, and the diaphragm becomes a fixed point depressing the soft tissues. The longer this condition continues the greater the danger of collapse of portions of lung tissue. The large mortality after tracheotomy and intubation is due to the postponement of operative interference in the majority of cases, until these changes have occurred. This assertion is verified by his own experience in tracheotomy. In his first ten cases, in all but one of which the operation was done as a last resort, none recovered. In the next seven cases in which, excepting two, it was done early, five recovered. The two fatal cases were not considered hopeful at the time of operation. His eighteenth case died before the trachea was opened. Of the last ten, five recovered. Twenty-eight cases with ten recoveries.

He has practised intubation in thirteen cases with six recoveries. All but one of these cases were seen in consultation, and some of them were in a dying condition when intubation was practised. In no case did death occur in less than twenty-four hours, and in all the relief from the dyspnœa was prompt and permanent. The youngest child was eighteen months of age, and died on the fifth day of convulsions. The youngest child to recover was aged two years. In one case of recovery tracheotomy was performed the day following the intubation. A smaller size tube than suited for its age had been used; the dyspnœa recurring and the tube absent from the glottis, it was feared that it had been passed into the trachea. It was found that the tube was coughed up and swallowed, and passed per anum two days later. Of course, in this case, little can be claimed for intubation.

He prefers intubation to tracheotomy, and believes that the former will supplant the necessity of doing the latter. The advantages are: It is free from danger, it requires no cutting or anæsthetic. The after-treatment does not require skilled attention, as the air is moistened and warmed by the natural passages before entering the trachea; there is, therefore, no mucus accumulating in the tube, and not the same danger of secondary inflammatory lesions. As the tube does not fill up the calibre of the trachea, membrane is coughed up around instead of through it, and thus the danger of blocking is avoided.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, January 28, 1887.

The President, J. C. Cameron, M.D., in the Chair.

MYXŒDEMA COMING ON DURING THE COURSE OF CHRONIC TETANY.

Dr. Stewart exhibited a man, aged forty-one years, who had suffered during the past six years from tetany. The contractions, which affect the muscles of the hands and face principally, usually come on monthly, and last from two to six days. During the past year, however, the tetanic symptoms have not been so severe or so frequent as formerly. This change, which was at first attributed to the treatment employed (galvanism and perchloride of mercury), is more likely due to a change in the course of the disease, possibly to a more advanced stage.

About eighteen months ago it was noticed that his speech was slow. He complained that it was difficult for him to answer a question at once. Œdema of the extremities and face is now apparent; it is of a solid character, not pitting on pressure. He complains of general numbness. The hands have the broad, spade-like shape so constant a feature of myxœdema. There is no thyroid gland tissue to be made out. The skin is dry and harsh. His temperature is almost constantly subnormal.

The symptoms at present may be summarized as follows: 1, profound anæmia; 2, slowness in thinking; 3, slowness in speaking; 4, slowness in moving; 5, solid œdema; 6, atrophy of the thyroid; 7, subnormal temperature; 8, harsh and dry skin.

Before the development of the mucinoid state, and during the tetanic period, there was marked increase in the electric irritability of the nerves to galvanism; 0.25 of a milliampère was sufficient to bring about contraction of the muscles supplied by the facial. It now takes 1.25 of a milliampère to induce a similar contraction; the KSZ = AOZ. With the exception of a slightly diminished quantity of urea, the urine is normal. No relative increase in the number of leucocytes, no diminution of red, no enlargement of spleen or lymphatic glands.

The reader of the paper remarked that this, so far as he knew, was the first recorded case of myxœdema following or coming on during tetany. Dr. W. Ord, about a year ago, read the details of a case of myxœdema before the Medical Society of London, where there was persistent flexion of the arms. This condition is, however, entirely distinct from typical tetany.

The case under observation is not unlike the condition seen in the monkeys from which Mr. Victor Horsley removed the thyroid. When they lived several weeks the preliminary tetany stage gave place to a mucinoid condition (myxœdema). Horsley and others believe that myxœdema, both surgical and idiopathic, is due to removal or disappearance of the thyroid. The ultimate cause of tetany is attempted to be explained in the same way. If this is so, why does not removal of the thyroid always bring on myxœdema? It is only in a very small percentage of the complete removals that it sets in. In Billroth's forty cases of complete extirpation there was not a single case. The cause is more likely to be found in injury or damage to the sympathetic. The atrophy

of the thyroid gland is, according to this view, a symptom and not the cause of myxœdema.

Dr. T. Wesley Mills said that to believe that any gland or other organ existed to prevent the formation of a substance, whether normal or abnormal, is inconsistent with general physiological principles. True, the removal of certain glands, as the testicles in the young, arrested development, both physical and psychical. In the adult dog such removal is followed by obesity, which can be largely accounted for by the inactivity of the animal, associated with the psychical shrinkage, the curtailment in the number and variety of the afferent impulses reaching the nerve-centres. It has been asserted that after the removal of the thyroid in children there is stunted development, especially intellectually. Dr. Mills thought it likely that metabolic changes follow the removal of the thyroid, owing to the influence on the nervous system, for there is a loss of balance; all healthful life implies balance of function. It is not yet clear how the balance is destroyed by removal of the thyroid, but we are on the way to knowledge, for we have learned, experimentally, that this organ is not a blood-former. If, as has been suggested, the changes following experimental or surgical removal are due to injury of the sympathetic, one would expect to observe vasomotor symptoms. This has not been the case, though such an objection must not be too strongly insisted upon, for though dilatation follows section of the cervical sympathetic, it is not permanent, and, if transient, may be overlooked.

Dr. Richard MacDonnell said that the patient had been under his care in the Montreal General Hospital for some time, during which he had been carefully observed, and no symptoms of tetany were ever present; but he understood Dr. Stewart to say that he had himself seen the man in a tetanic fit. He thought the case a doubtful one of myxœdema, and would not be prepared to say that the thyroid gland was absent; in many it is difficult sometimes to make out the gland by external manipulation.

Dr. Shepherd could not agree with Dr. Stewart's suggestion that the reason myxœdema or cachexia strumipriva follows excision of the thyroid is because of the disturbance damage done to the sympathetic system, as this affection, so far as he knew, never follows the extensive operations in the neck (as removal of chains of enlarged glands and tumors), when the sympathetic trunk is quite as much interfered with as in the operation of removal of the thyroid. Those cases which do not become myxœdematous after removal of the thyroid, are now supposed to be cases of incomplete removal, or where abnormal outlying portions of the gland have been left behind.

(From our Special Correspondent.)

Permanent Suture of Bones.—Dr. F. Guermonprez, of Lille, has been recently advocating the permanent suture of bones. Steel threads he finds are durable and supple, but not antiseptic; silver and platina threads have the same qualities as steel threads, and are moreover antiseptic. Threads made with fibres of vegetable origin cannot be employed for permanent ligatures. Among the threads formed from animal substance he finds that catgut is inefficient in osseous suture. Silk is badly tolerated by osseous tissue. Thread made of whale's tendon is formed of fibres wound round each other as the best ropes and cables are made. If silkworm gut is macerated during six weeks in carbolic solution (2 to 5 per cent.) its antiseptic property is insured.

Dr. P. Bigo, of Caudry, communicated the following details concerning osseous suture to the *Société de médecine de Strasbourg*. A child, six and a half years old, fell from a height of thirty-three feet on the 13th of July, 1885. There was cerebral contusion, and the child was unconscious during ten days; the two bones of the left forearm were fractured, close to their lower extremity; there was also compound fracture of the two bones of the right forearm. Notwithstanding treatment, a pseudarthrosis of the right arm remained.

On January 13, 1886, MM. Guermonprez and Duret performed a resection. Four days after the operation the drain of the ulnar wound was removed; that of the radial wound was reduced to half its length.

On the eleventh day all the stitches made by the cutaneous suture, and the remaining portion of the drain, were removed. Reunion was obtained without difficulty.

On the sixty-sixth day consolidation was complete; the actions of pronation and supination were effected, the child could write, and raise objects, by holding the limb in a horizontal direction.

There was no induration, nor any callus, at the level of the osseous sutures, which had been effected with silkworm gut. The limb was freed from every apparatus and dressing.

M. Duret in treating a club-foot recently practised cuneiform resection of parts of the cuboid and the neighboring bones. Seven suture stitches with single threads of silkworm gut were inserted, and adjustment was satisfactorily effected. The reunion of the skin was obtained without difficulty, and the osseous tissue tolerated the silkworm gut. This material is, therefore, preferable to others in permanent bone sutures. It is tolerated as well as catgut and the best metallic threads; and, if used double, is quite as solid.

Medical Practice in China.—From a recent report of St. Luke's Hospital, at Shanghai, we learn the following regarding the diseases of the Chinese: As might be inferred, the most common forms of disease are malarial, and nearly every disease is more or less modified by this prevailing influence. Intermittent, remittent, and typho-malarial fevers are very common. Both adults and children suffering with enlarged spleen are encountered every day. There is a very remarkable predominance of the *quartan* type of intermittent fever, just the reverse of what occurs in malarious districts in the United States. Again, the paroxysm of fever is most likely to come on in the afternoon, or at night, thus differing from what we see at home. Next in frequency are diarrhœa, dysentery, and liver troubles—abscess of the liver is not uncommon. Nearly all the zymotic diseases flourish. Smallpox is spread every winter by the custom of inoculation. This is done by putting the variolous matter on a rag and inserting it up one nostril. No care is taken to isolate patients suffering from this

disease. Measles are very common, and it is a well-known fact that one attack of measles here is no protection from the disease at home. The same statement has been made about whooping-cough; this, however, lacks confirmation. Typhoid fever claims many victims—especially in the autumn. Typhus occurs from time to time. A few cases of Asiatic cholera occur among the Chinese every year. Occasionally the disease takes on an epidemic form, then hundreds and thousands are swept away. The general idea amongst the foreign doctors here seems to be that water is the most common vehicle for the spread of this disease. The idea that great care in the preparation of food and drink is the best prevention of an attack of cholera, seems to be borne out by the comparative freedom from cholera enjoyed by foreigners, though they live here subject to the same conditions as to climate and surroundings as the native population. The few foreigners attacked are usually sailors or others who are exposed to the evil effects of bad food and impure water. A striking example of what can be done in the way of prevention in this disease came under the observation of the writer. During the height of the worst cholera season which has been seen in Shanghai for the last twenty-five years, a man-of-war arrived in port with orders to remain here. The commanding officer and the senior surgeon had the good sense to work in unison for protection against the spread of the disease. No one was allowed on shore except on official business, the boats' crews were not allowed to land, no one slept on shore. Only distilled water was used, no fruit or vegetables were allowed on board, Officers and men lived on the ship's stores. This vessel remained six weeks in port and finally went to sea. Not one case of cholera appeared on board. This ship was moored right in front of the foreign settlement. She was surrounded by other men-of-war. The writer saw burial parties leaving early every morning from the other ships and knew that their crews were decimated by the cholera. Seven hundred foreigners, mostly from the shipping, fell victims to the cholera during this season. None of the other ships took the precautions observed by the ship I speak of. These are facts: they can speak for themselves. Owing to the coarse, badly prepared food of the poorer Chinese, consisting for the most part of salted fish, or stale bacon, mouldy beans, pease, rice, sea-weed, and cabbage, dyspepsia in all its protean forms is common. All diseases of the eye prevail—conjunctivitis, granular lids, entropion, and pterygium are the most common forms. In this part of China the people seldom consent to an operation on the eye, demanding to be cured by the application of medicine alone. A few submit to operations. Almost every medical report written in China speaks of the universal prevalence of skin diseases, specially the parasitic varieties. This is very truthfully attributed to the want of cleanliness. Still, a large number of non-parasitic complaints are found, and, I think, not enough stress has been laid upon the overcrowding, foul air, and poor nourishment as factors in the production of these diseases. This is shown by the readiness with which they yield to treatment when admitted to the wards of the hospital. Here, in addition to the baths and clean clothing, they have pure air, good food, and cheerful surroundings, which do quite as much, or more, for the cure of these complaints as the medicines administered. Beri-beri is not uncommon, many patients have it in a mild form which shows a tendency to recovery during the winter months; relapses, however, are frequent. When the patient is attacked with the severe form of the malady, with marked numbness of the extremities and round the mouth, pains in the legs and general anasarca, residence in a hill country seems to offer the only chance of relief. The Chinese are peculiarly liable to the formation of large abscesses. The most common are those in the subcutaneous areolar tissues of the chest, back, and the upper and lower extremities. These abscesses frequently attain an enormous size before the patients apply for relief. Post-pharyngeal, psoas, lumbar, perityphlitic, perinephritic, abscesses in the sheath of the rectus abdominis muscle, and, in fact, every variety of abscesses are much more frequently encountered here than they are at home.

OBITUARY RECORD.—FENNER HARRIS PECKHAM, M.D., one of the oldest and best known physicians in Rhode Island, died at his home in Providence, on the 17th of February.

He was born in 1820, in Killingly, Conn. His father, Dr. Hezael Peckham, was an able and noted physician. The son was graduated from Yale Medical College in 1842, and practised in East Killingly—now known as Putnam Heights, till 1852, when he removed to Providence, when he at once acquired a large practice.

He became a Fellow of the Rhode Island Medical Society and was for two years its President. Besides addresses and reports of special cases, he was the author of a monograph on "Hydrophobia," read before the American Medical Association, and also one on "The Topographical and Geological Condition of the Second District of Rhode Island." For several years he was physician to the Marine Hospital at Providence.

In 1861, he was commissioned Surgeon of the Third Rhode Island Heavy Artillery Regiment.

In 1863, he was appointed Surgeon of the Board of Enrollment of the Second District of Rhode Island. The cause of death was chronic Bright's disease, from which he had suffered for nine years, during which period he had not been in active practice.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 22 TO FEBRUARY 28, 1887.

HUNTINGTON, DAVID L., *Major and Surgeon.*—Ordered for duty at San Diego Barracks, California, and granted leave of absence for [illegible]. Major [illegible] *S. O. 45, A. G. O.*, February 25, 1887.

WHEAT, JOSIAH H., *Captain and Assistant Surgeon.*—On being relieved by Major Huntington, to proceed to Angel Island, California, and report to commanding officer for duty at that post. —*S. O. 45, A. G. O.*, February 25, 1887.

TESSON, LOUIS S., *Captain and Assistant Surgeon.*—Ordered for duty as attending surgeon at Headquarters, Division of the Missouri [illegible]. *S. O. 44, A. G. O.*, February 23, 1887.

BARROWS, CHARLES C., *First Lieutenant and Assistant Surgeon.* [illegible] to take effect February 17, 1887. *S. O. 42, A. G. O.*, February 23, 1887.

HALL, CHARLES H., *First Lieutenant and Assistant Surgeon.* [illegible] Texas [illegible] Texas. *S. O. 45, Department of the Gulf*, February 25, 1887.

MASSEE, HARRY H., *First Lieutenant and Assistant Surgeon.* Relieved [illegible] Department of Dakota (March 25, 1887). *S. O. 43, A. G. O.*, February 25, 1887.

EXCISION OF THE KNEE.

A clinical lecture delivered at the Pennsylvania Hospital

BY JOHN H. PACKARD, M.D.,

SURGEON TO THE HOSPITAL.

GENTLEMEN: I have to-day to bring before you a case in which the operation of resection or excision of the knee-joint is called for; a case in which the articulating ends of the femur and tibia are so spoilt by disease, the result of injury, as to render the restoration of the normal state of the joint hopeless, and to necessitate surgical interference.

This little fellow, eleven years of age, says that he hurt his left knee by a fall, about six weeks before his admission to the hospital, which was on the 24th of November, 1886. For several days after the accident, he ran about and played, but was then compelled, by increasing lameness, to give the limb rest. The knee became swollen and flexed, and very painful on the slightest attempt to extend it; the skin remained natural, but was traversed by a few large superficial veins.

On the 2d of December, Dr. Roberts, who had charge of him, had him etherized, and forcibly extended the leg on the thigh. That evening his temperature rose to 103.6°, but it gradually fell again to normal. The knee, five days later, was in exactly the same condition as before.

The child's general health seemed good, but he was put upon the use of cod-liver oil, with syrup of lactophosphate of lime and syrup of iodide of iron. His appetite is now fair, and he sleeps well. This favorable state of things would not, however, continue if the local disease were allowed to run its course.

On examining the joint, we find it slightly swollen, tender, and somewhat hotter to the touch than that of the sound side. It is flexed at a right angle, and cannot be extended, the effort to straighten it causing severe pain. The patella is only very slightly movable. Note also the change in relation of the articulating surfaces; the head of the tibia has slipped backward so as to be applied to the posterior portion of the condyles, so that these latter processes seem to project forward as a double rounded mass. But although the hinge-motion of the joint is gone, there is undue lateral mobility; that is, when I grasp the thigh with one hand, and the ankle with the other, I can sway the foot from side to side as I could not if the lateral ligaments of the knee-joint were sound.

You will, of course, perceive that even if we could from this moment set aside the inflammatory process in this joint, and cause union to occur between the joint surfaces, the boy would be hopelessly crippled. We, therefore, propose to relieve the inflammation and give the limb a useful shape, by the excision of the diseased joint.

Excision consists in laying open the joint, sawing off the diseased bones, removing all degenerated synovial membrane, placing the sawn ends of the bones accurately in contact, and closing the wound in the skin. By proper appliances we then keep the parts supported until union has taken place between the bones. In the elbow or shoulder, we try to get mobility; but in the knee, the value of the lower limb consisting in its firmness as a support for the body, this would be a disadvantage. I am aware that surgeons have sought to obtain a movable joint at the knee, but cannot now recollect having seen any report of a thoroughly satisfactory result of such an attempt.

It is of much importance, if possible, to saw through the epiphysis only, so as to save the epiphyseal junction, in order that the subsequent growth of the bone may not be interfered with; hence the slice removed from each bone should be as thin as it can be made, to embrace all of the diseased portion.

Some ingenuity has been bestowed upon the method of dividing the bones. Thus it has been proposed to saw the end of each bone in two planes at an angle to one another; the planes in one bone forming an entering, in the other, a projecting angle. My own practice has always been to carry the saw directly across each bone, but slightly slanting the blade, so as to cut each at the expense of its posterior portion; thus when united they form a very slight angle forward, which facilitates walking by enabling the patient to get some spring forward on the toes. I think the gait thus secured is decidedly better than that obtained by placing the limb perfectly straight.

Operations on the bones and joints are among the surgical procedures most distinctly concerned in the benefits of the modern antiseptic methods. Especially is this true of excision of the knee. Under the former practice, free suppuration was inevitable, and the dressings had to be changed daily. To avoid the disturbance of the limb which this involved, I, many years ago, devised a splint of which the thigh and leg portions were bracketed together, while that corresponding to the knee was arranged as a shelf to slide in and out. Under the antiseptic system this provision is needless. The dressings are not to be disturbed, unless for some special reason, for several weeks.

The child being now etherized, and the limb thoroughly cleansed, an Esmarch bandage is applied. This, like everything else which is allowed to come in contact with the part to be operated upon, has been depurated by means of the solution of bichloride of mercury.

On opening the joint at the side of the patella, you perceive at once a grayish-yellow, puffy mass protruding. This indicates a condition of the synovial membrane known as gelatinoid degeneration. I now carry an incision across the front of the joint, through the

ligament of the patella, from one side to the other. I now separate the ends of the femur and tibia, and you see the inflamed and eroded state of the articular cartilages, with a small amount of ill-conditioned pus, and a fringe of broken-down tissue about their margins. I divide the crucial ligaments, strip down the periosteum, and apply the narrow blade of a Butcher's saw at the back of the tibia. Cutting from behind forward, I remove a thin slice of the bone.

I now do the same at the lower end of the femur. Note the peculiar grayish-yellow color of the sawn surfaces, and that on that of the tibia there is a small patch which is softer and paler than the rest. When the constricting elastic band round the thigh is removed, you will see the healthy red color of the marrow return.

Now I dissect out the patella from the fibrous envelope constituted by the tendon of the quadriceps. This little bone would be useless if left, and might give rise to trouble, so that it is much better out of the way. The elastic band is now loosed from about the thigh; the bone-marrow becomes red, and the edges of the skin swell up, and a rather free flow of blood occurs, but soon slacks. No vessels appear of sufficient size to require ligation.

With this spoon-shaped, sharp-edged curette, I now scoop out the small patch of soft and diseased bone from the sawn surface of the tibia, and scrape away all the dirty, sloughy tags of serous membrane and fibrous tissue. Two sinuses extend, one from the outer side of the joint an inch or two upward along the femur, the other from the inner side of the joint a scant inch downward along the tibia; these are also curetted, and through a counter-opening at the extremity of each, a drain of several strands of fine carbolized catgut is passed, filling up the whole tract. A small pledget of the same material is packed into the cavity where the sawn end of the tibia was scraped.

The bones are now ready to be apposed, and when this is done you see that they fit accurately together; that the lateral outlines of the limb are correct, and that when looked at from the side there is seen to be a very slight angle between the axis of the thigh and that of the leg. In order to keep the sawn surfaces exactly together, I now drill each bone at two points, from the anterior wall obliquely to the sawn surfaces, and through each pair of these drill-holes I pass a suture of thick chromicized catgut, and tie it firmly. The introduction of these thick catgut sutures through the drill-holes is sometimes, as you have seen on one or two previous occasions, a matter of difficulty. I have, therefore, provided each of these with a silver-wire guide, the gut being pierced near its end with the wire, which is then wrapped around it and twisted, leaving one long end. This wire being first passed through the drill-holes, the gut is drawn after it, as you see, with the utmost ease.

The wound in the skin is now carefully closed from end to end with carbolized catgut sutures; the protective is applied, then iodoform gauze, and borated cotton, with an antiseptic gauze bandage over all. Now the limb is carefully bandaged to a Day's posterior splint, padded so as to correspond exactly with the outline of the parts. Finally, the limb, thus secured, is placed in a cradle made with a Smith's wire frame splint, for the purpose of suspending it so that the child can change his position in bed without doing any harm. The suspension is made in the ordinary way, by means of a gallows-frame with a pulley sliding in the cross-piece, and a cord and tent-block.

(On the evening following the operation, the child's temperature ran up to 102.4°; and on each of the four ensuing evenings it reached a little over 100°. After this it scarcely varied from the normal. January 19th, the dressings were removed, with the idea that there might be some local cause for the slight evening rise in temperature; but none was found. On the 2d of February, the eighteenth day, the limb was dressed before the class, and found in the most satisfactory condition; the wound soundly healed, and a very marked degree of firm union between the bones.)

ORIGINAL ARTICLES.

PAROXYSMAL CARDIAC DYSPNŒA.[1]

BY ALFRED L. LOOMIS, M.D., LL.D.,

[redacted]

In very many of those valvular diseases of the heart which are accompanied by hypertrophy and secondary dilatation, dyspnœa is a prominent symptom. Under such circumstances, however, the dyspnœa is of gradual development, is often, and indeed usually, more or less persistent, and depends rather upon the secondary pulmonary and renal changes, than directly upon the cardiac lesion.

In the form of dyspnœa which I now propose to consider, and which I have designated paroxysmal cardiac dyspnœa, the difficulty in breathing is due entirely to the cardiac condition, and the consequent temporary slowing or permanent arrest of the blood current in the heart and pulmonary vessels. In this condition there are no organic or functional changes within the lungs to obstruct the entrance of air to the alveolar surfaces, and the disturbing element in the relations between the blood and air is, therefore, entirely upon the side of the vascular element, which becomes diminished in both quantity and rapidity. The symptomatic results, however, are similar in the two conditions, for the effects are the same, as is readily proved by physiological experiments, whether the air or the blood is prevented from entering the lung. Under whatever diseased conditions this form of dyspnœa may arise, it has this one essential cause, viz., a temporary or permanent arrest of the blood in the heart and pulmonary arteries, a condition which evidently must either be paroxysmal or speedily terminate in death.

When distinct valvular changes are present with consequent hypertrophy and secondary dilatation, a gradually developing chain of symptoms precedes and gives warning of the approach of more serious conditions, and the typical history of the case seldom allows of an error in diagnosis. But when, on the contrary, the entire history is one which does not direct attention to the heart, and the immediate symptoms are cerebral and neurotic, rather than pulmonary or cardiac, and when even a physical exami-

[1] Read before the New York State Medical Society, February 2, 1887.

nation of the chest shows few, if any, of the familiar or ordinarily recognized signs of organic disease, it is quite possible, and it often happens, that the exact nature of the case is not detected, or the dangers which attend it fully appreciated. It is just because it is so commonly the result of obscure cardiac changes, rather than valvular lesions, that I wish to emphasize its importance, and invite attention to its more careful study.

That the exact condition which I desire to present may be more apparent, I will briefly state the histories of two cases which seem to me, from a clinical aspect, to be typical, although the pathological lesions were essentially different.

Case I.—Mr. C., aged fifty-four, of sedentary habits, exceedingly temperate, having never been ill a day in his life, came into my house much out of breath, having ridden about a hundred miles in the cars that morning, and having walked quite rapidly from the Forty-second Street Depot (a distance of about half a mile). While waiting a few minutes in my reception-room his difficulty of breathing increased, and, as he attempted to walk across the hall to my consulting-office, I noticed that he staggered. As I took hold of his arm to steady him, the muscles were quite rigid; he was exceedingly pale, and was apparently unable to speak; as I placed him in a chair, a tremor passed over his body, and he immediately sprang up, braced himself against the corner of the mantle, and gasped out "brandy." When this was furnished he swallowed with difficulty; his head was thrown back, his face became deathly pale, with an appealing expression upon it, the surface of his body was covered with a cold sweat, his pulse was feeble and intermittent, at times imperceptible at the wrist. The efforts to breathe became more and more desperate, and as I steadied him—for he would not allow me to place him in a horizontal position—it seemed as if each breath would be his last. In about twenty minutes the paroxysm gradually passed away.

As soon as he was able to talk, he told me that he had had several similar seizures, but none so severe. When he was sufficiently relieved I made a careful examination of his chest. Normal respiration could be heard over the entire chest; both heart sounds were indistinct, and there was an entire absence of normal cardiac rhythm; three or four quick cardiac contractions were followed by a prolonged pause, which was lengthened when he held his breath; no cardiac murmur could be made out.

My diagnosis was degeneration of the ventricular walls, with dilatation of the heart cavities, especially the right.

The patient never entirely recovered from this attack, for after this, slight physical exertion would always bring on more or less severe attacks of dyspnœa; he never, however, had any œdema of the lungs, or of the extremities, and his urine was very albuminous.

A month after I first saw him, one morning, about four o'clock, he suddenly awoke in a paroxysm, and died in a few minutes.

At the post-mortem examination the walls of the right ventricle were found exceedingly thin, at points almost translucent, readily giving way under pressure. Microscopical sections at different points showed advanced fatty changes in the heart muscles. Both ventricular cavities were dilated, especially the right, and contained large exsanguinated clots, which were so interlaced with the chordæ tendineæ of the tricuspid valves, as to interfere markedly with the blood current. The walls of the left ventricle were pale, but of normal thickness, and showed comparatively little evidence of degeneration; the valves were normal, the lungs were pale and free from disease, the liver and kidneys were engorged, but otherwise healthy.

Case II.—A physician, aged sixty-eight, of the most abstemious habits, who had never been seriously ill, in December, 1882, had a severe pleuro-pneumonia on the left side, complicated by pericarditis, from which he slowly recovered. At the expiration of four months from the commencement of his attack, he was able to resume his active professional work, and seemed perfectly well for more than a year after, although there remained the evidence of quite extensive pleuritic thickenings and adhesions at the base of the left lung. He then began to suffer from attacks of paroxysmal dyspnœa, the attacks usually lasting about half an hour. They were usually brought on by physical exertion, mental excitement, or came on immediately after eating.

I saw him in one of these attacks: his face was pale and anxious, his surface cool, his breathing exceedingly difficult, the muscles of the neck and chest being fixed and rigid during inspiration, but he complained of no pain in the chest; his pulse was feeble, intermittent, and, at times, imperceptible.

A physical examination of the chest showed that there was no obstruction to the entrance of air into the lungs, and no sign of pulmonary congestion or œdema. The apex beat could not be felt, and the heart-sounds could not be made out; all was confusion over the præcordial space; no cardiac murmur was heard.

As the attack passed off, the heart-sounds became regular in rhythm and normal in character, except that the first sound was short and valvular.

In two hours after the subsidence of the paroxysm he said that he felt as well as usual, and claimed that it was only an attack of indigestion. I warned him of his danger, and tried to persuade him to give up work and live a quiet life. I prescribed for him, but he said that he did not believe in drugs; he therefore never took my prescription, but went on doing the same work that he had been doing for forty years.

Afterward I occasionally met him in an unprofessional way, and he always expressed himself as feeling well, except that he had to be very careful of his diet, and about going up stairs. One morning, about three o'clock, four or five months after, he awoke gasping for breath, and in a few moments was dead.

A post-mortem examination showed that all the organs of the body were in a normal condition, except his heart and the left pleura; the surfaces of the pericardium were closely agglutinated to each other, and there were firm adhesions between the

left pleura and pericardium; and at the lower third of the left pleura there were firm adhesions and extensive pleuritic thickenings. The heart cavities were distended with blood, showing that death occurred, or the heart stopped, during its diastole. There were no valvular lesions. Both coronary arteries were completely obstructed; in one the obstruction had evidently existed for some time; although the calibre of the other was diminished for an inch or more, it evidently had been pervious until a short time before death, as it was filled by recent thrombus. The aorta was slightly atheromatous. Section of the cardiac walls at different points showed quite extensive interstitial myocarditis, which seemed to be a part of the chronic pericardial changes.

CASE III.—About two months since, I was invited to visit a gentleman, sixty years of age, who was dead when I reached his residence, but whose previous history, as given to me by his physician, was similar to the one just related. In this case death occurred suddenly, immediately after the patient had rapidly ascended two flights of stairs. No post-mortem examination was made.

In studying the pathology of this form of dyspnœa I have found degeneration and thinning of the cardiac walls its most constant lesion; the degenerations in some cases were fatty, in others fibroid; and in one case, which occurred during convalescence from typhoid fever, simple softening. In every instance the degeneration commenced in the right ventricular walls, or was more advanced there than in the left.

Together with the changes in the heart walls in some of my cases, there was atheroma of the aorta and of the aortic valves, accompanied by more or less disease of the coronary arteries. In two instances the coronary arteries were completely obstructed.

Whenever any of these degenerative changes in the cardiac walls has reached an advanced stage, especially if it is associated with extensive atheroma of the aorta, attacks of cardiac dyspnœa may occur from very slight exciting causes.

But it not unfrequently happens that the signs of such cardiac failure may be often repeated without a fatal paroxysm, until some obstacle is developed within the heart cavities to obstruct the passage of blood, and so to embarrass an already feeble heart that it cannot recover itself.

A frequent cause of death, under such circumstances, is the formation of exsanguinated fibrinous masses, which become entwined around the chordæ tendineæ of the tricuspid or mitral valves.

It seems probable, in such cases, that there is time and opportunity during the stasis of blood in the ventricles, which results from the imperfect and feeble ventricular systole occurring at the commencement of an attack, for the formation of cardiac thrombi. As the heart recovers the filaments of fibrin become separated, and interlace themselves with the chordæ tendineæ. The curtains of the valves are thus held in the valvular opening, and there results a complete arrest of the blood current through the heart, which leads to sudden death.

In some instances I have found both the right auricle and ventricle filled with exsanguinated coagula, which sent prolongations into the pulmonary artery, and obstructed the blood current to the lungs. In one instance, a large pericardial effusion, by its pressure on the heart, arrested cardiac contractions, and thus prevented the passage of blood to the lungs.

I have a specimen where death occurred suddenly on the third day of an acute lobar pneumonia, in which a thrombus entirely filled the cavities of the right auricle and ventricle, the heart being, in other respects, healthy.

In every case of paroxysmal dyspnœa terminating in death, which has come under my observation when I could obtain a post-mortem examination, there was unmistakable evidence of a mechanical arrest of the circulation in the heart, either from failure of its muscular power, or from obstruction to the current of blood through the heart, by fibrinous masses in its cavities.

In the majority of instances the arrest is in the right heart, and, as a result, the blood is shut off from the pulmonary artery; the lungs, under such circumstances, will not only be free from congestion, but bloodless, while the other internal organs will be found intensely congested. If the obstruction is in the left heart, the blood current will be arrested in its passage to the aorta, then the lungs will be intensely engorged, and the other internal organs will contain less than their normal amount of blood.

It seems to me reasonable to believe, that the primary or predisposing cause in all cases of paroxysmal cardiac dyspnœa, is a gradual failure in the organic power of the heart, that the exciting cause of the paroxysm is anything which will lead the heart failure to an entire suspension of the cardiac circulation. Thus when any form of degeneration of the cardiac walls exists, mental shock, excessive physical exertion, violent passion, or sudden fear, may act as an excitant of the paroxysm. These excitants may differ widely from each other, for a feeble heart may be stopped as readily by a call for stronger action which it is not prepared to meet, as by suddenly cutting off its blood supply by obstructing its nutritive vessels.

During the relaxation of the physical forces which comes in the early hours of the morning, after profound sleep, when the heart, in the perfectly healthy state, has its minimum propelling power, is the period in the twenty-four hours when one with degenerated heart-walls is most easily affected. Often such persons will awake about four in the morning in the midst of a paroxysm of dyspnœa. In the two instances which I have related, death occurred almost instantaneously about that time of the day.

A distended stomach from flatulency or any other cause, produces little inconvenience in a healthy person beyond a sense of fulness or slight pain, but in one with a degenerated heart, when a distended stomach presses on the diaphragm, the inspiratory movements become impeded, the pulmonary circulation embarrassed, and the enfeebled heart enters on a struggle for which it has no reserve power, and a more or less severe paroxysm of cardiac dyspnœa is the result.

A fully developed paroxysm usually comes on with a sense of constriction across the chest, which is immediately followed by a struggle for breath, accompanied by spasmodic contractions of the respiratory muscles, the surface of the body becomes pale and cold, the countenance extremely anxious, and the patient, if the paroxysm is not too severe, is constantly changing his position, with the hope of obtaining relief. Painful muscular spasms occur in the voluntary muscles in different parts of the body. The mind remains clear. The pulse is feeble, irregular, and intermittent, and frequently there will be a prolonged absence of the radial impulse. This, as well as other forms of cardiac dyspnœa, presents a peculiarity in the relation of pulse and respiration as distinguished from all other forms of difficult breathing, in that the return of the pulse precedes instead of follows the subsidence of the dyspnœa. In some cases the patient will complain of pain at the lower portion of the sternum, which shoots through the chest to the back.

If death takes place during the paroxysm, the final act is one of persistent muscular contraction, the heart-failure being followed by a tonic spasm of the muscles of the chest, and a rigidity of all the voluntary muscles.

The symptoms which precede an attack, or what may be called its preliminary symptoms, are few, but they are diagnostic. One of the earliest and most constant, and one which may exist for months and perhaps for years before the occurrence of a well-marked paroxysm, is a sinking or exhausted sensation in the præcordial region; this sensation will come on from very slight causes, such as sudden physical exertion, or strong mental emotions. At first a diffusible stimulant, a few swallows of hot water, or a recumbent posture will relieve it.

In some instances the patient will complain of a choking sensation, commencing in the cardiac region, and passing rapidly to the pharynx, which usually comes on immediately after taking food, or at the moment of falling asleep; it is often very oppressive, and to nervous subjects alarming. So-called dyspeptic symptoms will often accompany it. Sooner or later there will be established an irregularity in the cerebral circulation indicated by attacks of vertigo, headache, hissing sounds in the ear, and occasional dimness of sight. For a long time these symptoms may cause the patient no serious inconvenience, but eventually a series of obscure nervous phenomena will develop, he will become irritable, melancholy, and perhaps hypochondriacal, and he will very likely be treated for neurasthenia, or perhaps congestion at the base of the brain. At length attacks of faintness with pallor will occur, and the patient will be troubled with insomnia, his mental faculties will be disturbed, and slight physical exertion, as going up stairs, will cause breathlessness.

In one who presents these symptoms an attack of paroxysmal cardiac dyspnœa is liable to occur at any moment. The physical signs, if the general symptoms are well marked, are usually distinctive; the cardiac impulse is feeble and difficult to locate, there is usually an epigastric tremor, the heart's action is irregular in force and rhythm, although the patient may not be conscious of its irregularity. The first sound of the heart is short and valvular in character, and during periods of great cardiac irregularity it is difficult to distinguish the first from the second sound.

In the majority of cases there are no cardiac murmurs, and no evidence of valvular insufficiency. There will be an entire absence of any pulmonary disease adequate to produce the general symptoms, and an examination of the urine will usually give negative results. These patients will become exceedingly anxious about themselves, and will consult one physician after another, without obtaining anything more than temporary relief.

When a well-defined paroxysm has once occurred, little can be done to avert a fatal issue, but much may be done to delay the occurrence of the first paroxysm, or rather to arrest the degenerative changes in the heart-wall, and prevent the sudden dilatation of its cavities which so often leads to the first paroxysm. This must be accomplished mainly by a restricted diet, and by a carefully regulated life. There is perhaps nothing which so certainly induces the degenerative changes in the cardiac muscles, that allows of sudden dilatation of its cavities, as the daily intemperate use of alchohol; it is evident in such cases that its intemperate use must be stopped, but never suddenly or entirely, for a moderate amount of alcohol is essential to the nutritive processes in a chronic alcoholic subject.

In all cases the diet should be restricted to milk, meat, and a small amount of bread; sugars and starches should be avoided and the quantity of food taken at any one time should be limited. Flannel should be worn next the skin, and the surface of the body should never become chilled. Each day should be divided into eight hours for sleep, eight hours for labor, and eight hours for rest and refreshment, and this division should be strictly adhered to. In other words, the entire life of the individual should be carefully regulated. Next to diet, the most important thing is systematic daily exercise in the open air; the exercise should never be violent or carried to fatigue; commencing in a moderate way, it should be daily increased until the individual is able to take long walks without fatigue, avoiding elevations and going up stairs.

The medical treatment resolves itself into alkalies as eliminatives; the different preparations of iron as tonics, in combination with which small doses of digitalis should be given, five or ten drops of the tincture twice a day. In alcoholic subjects strychnine should be combined with the iron. All of these drugs should be given in such small doses that their use may be continued for a long time.

The first thing in the management of a paroxysm is to give the patient plenty of fresh air, the second is to keep him in a semi-recumbent posture, the third to apply artificial heat to the surface of the body. The only two medicinal agents which I have found to have any positive control over a paroxysm are the nitrite of amyl and nitroglycerine. After one paroxysm has occurred nitroglycerine should be given whenever the premonitory symptoms of

an attack are present. During a paroxysm nitrite of amyl carefully administered will give at least temporary relief. I have patients who carry pearls of the nitrite of amyl constantly with them, which they use to ward off impending attacks.

THE PHYSIOLOGICAL ACTION OF SPIGELIA, OR PINKROOT.

BY H. A. HARE, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

NOTWITHSTANDING the fact that several writers have described this drug from a clinical standpoint, no one, so far as I am aware, has ever studied its physiological action.

In the human being the drug is said to produce symptoms closely resembling those produced by any of the mydriatics, such as flushing of the face, dryness of the skin, and talkative delirium. Only two cases of fatal poisoning in man have ever been reported, and these have passed from text-book to text-book till the original report has been lost.

When as much as three ounces of the fluid extract of spigelia is given by the stomach to a large dog weighing forty pounds, the following symptoms appear: Almost immediately after the ingestion of the dose the animal has short and quick expiratory movements, amounting almost to a cough; soon after the pupils become widely dilated, and at the same time very marked internal strabismus asserts itself; the eyes becoming fixed in this position so that they cannot follow any object, such as a pencil, when it is passed from side to side. Constant retching, with no result, now comes on, the animal standing, and apparently suffering from no sensory or motor palsy. There is no change in gait. Soon after this marked exophthalmia develops itself. The retching having lasted about five minutes, now passes off, and at this time signs of muscular weakness and lack of co-ordination appear; the walk becomes staggering in both fore and hind legs. The respirations now become very rapid, resembling those of a dog after a long, hot run, the tongue hangs from the mouth and is dry and red, and the nose is hot and no longer moist. Muscular power is progressively lost, so that the dog frequently falls when endeavoring to walk, but sensation does not seem to be affected. About this period the animal lies down and passes into deep sleep, which in turn soon passes into coma, and death follows without any movement being made, evidently from a general failure of vital force. The respirations, as death approaches, become slow, and are finally extinguished consentaneously with cardiac arrest.

In the frog the same symptoms occur as in the higher animal, including the marked exophthalmia and to a less degree the strabismus. The fixation of the eyeball is extreme, and it feels to the finger like a hard knob, which the lid cannot cover. Muscular weakness with dropping of the jaw comes on, and motor power is constantly decreased, until the batrachian lies relaxed and powerless. That the action of the drug in thus destroying motor power is spinal, was proved by the following experiments: If the hind legs are protected from the poison by ligation of the abdominal aorta, the palsy is as great as under ordinary circumstances, and reflexes are totally abolished. Further, if the spinal cord be directly galvanized no movements occur in the hind legs; and, lastly, if strychnia be injected into the body, even in large amount, its action is not only slight, but occurs after the lapse of many minutes. That the drug has no action on the motor nerves is proved by the fact that when the poison reaches the efferent nerves, either through the circulation, or when directly applied, galvanization of the nerve trunks causes normal contractions in the tributary muscles, and the sensory nerves likewise escape, for if the drug be applied directly to the nerve and the foot irritated, signs of pain are elicited, and reflex movements occur. Further than this, if the vein in the leg be tied, and the drug injected into the limb, thus protecting the spinal cord, reflexes occur on irritation of the drugged foot.

That the palsy is not cerebral is proved by the fact that movements of muscles supplied by the cranial nerves continue long after the movements in the legs have ceased, and by the other experiments already detailed.

The action of the drug on the circulation is as marked as its effects on the nervous system, and on the cardiac muscle it acts as a direct depressant poison, for if it be injected into the jugular vein in such a way as to come suddenly in direct contact with the heart the movements of that viscus almost instantly cease. Further than this, if the excised heart of the frog is dropped into a strong solution of the drug its movements are almost immediately stopped in a condition of diastolic arrest, although the relaxation is not very marked. When a frog receives as much as twenty minims of the extract of spigelia the heart is slowed to a considerable extent, as much as ten or fifteen beats per minute, and diastole, while not increased in length, is nevertheless very full and marked. The change from systole to diastole is abnormally rapid, so that the heart in one moment in systole springs with a quick movement to its full diastolic condition. Systole, however, gradually increases on diastole, in much the same manner as in digitalis poisoning, until finally the greater portion of the ventricle fails to dilate, the apex being tilted more and more forward while the ventricular walls are powerfully contracted. As the systolic pauses increase, the diastolic movements decrease in volume, until finally the heart dilates no more than it does normally. At this time the powerful and heretofore spreading systolic contractions seem to lose power and the heart shortly stops all movement in a semi-relaxed state. Experiments on the warm-blooded animal show that on the injection of one drachm, or less, of the drug the action of the heart is very rapidly slowed in its movements, and that this slowing is chiefly due to central inhibitory stimulation as shown by the fact that if the vagi be cut before the drug is given this slowing does not occur, and also if after the drug has slowed the heart the vagi be cut the inhibition no longer remains. That the fall of arterial pressure produced

by this drug is due in great part to the cardiac depression which it produces is proved, since asphyxia will cause a rise in pressure, and that the pressure returns nearly to normal as soon as the heart gets rid of the drug which has been suddenly injected into it. On the respiratory centre the drug seems to have a still more depressing influence, respiration ceasing some moments before the cardiac arrest.

These experiments were repeated again and again in order to avoid erroneous conclusions. The extract used was prepared by Milton Campbell, druggist, Twenty-first and Pine Streets, of this city.

BACTERIOLOGICAL NOTES.

By GEORGE M. STERNBERG, M.D.,
MAJOR AND SURGEON, U. S. ARMY.

The Bacillus of Glanders. (*Bacillus Mallei.*)

The researches of Löffler and Schütz,[1] published in 1882, established in a definite manner the etiological relation of the minute bacillus found by them in the diseased tissues of infected animals, to the disease known in this country as glanders, Ger. *Rotzkrankheit*, Fr. *Morve*. This has been confirmed by the independent researches of Israel,[2] by the subsequent experiments of Weichselbaum,[3] and of Kitt,[4] and by the more recent investigations of Löffler.[5] All of the observers named agree in describing this bacillus as a slender rod, somewhat resembling the tubercle bacillus, but of more uniform size and somewhat broader.

According to Flügge,[6] in stained preparations the rods usually appear to be made up of dark and bright portions, which under a low power give the impression of a chain of cocci. Flügge supposes that the bright, unstained portions of the rods represent spores. Löffler has not been able to convince himself of the presence of spores, although he has found that development may occur after three months from bacilli which have been kept in a desiccated condition. The same author has found that exposure to a temperature of 55° C. (131° F.) for ten minutes is sufficient to kill the bacilli. This fact is opposed to the view that the bright spaces in the rods are spores, as Flügge has inferred. According to Weichselbaum, the Rotz bacillus forms spores. Evidently this is a question which cannot yet be considered definitely settled.

The bacilli are endowed with active movements (Eisenberg), and grow readily in a variety of culture-media—on blood-serum of the horse or sheep (not so well on that of the ox), on agar-agar, and flesh-peptone-gelatine, and in neutralized infusions of the flesh of the horse, the sheep, the ox, the rabbit, the dog, etc. Cooked potato furnishes an especially favorable soil upon which to cultivate the bacillus of glanders. Growth occurs upon these in two or three days at a temperature of 37° C., in the form of a thin, brownish, slimy layer. According to Weichselbaum and Kitt, growth also occurs, although very slowly, at the room-temperature (25° C.).

Upon blood-serum, at 37°, growth occurs in three days, in the form of numerous little transparent drops scattered about on the surface (Eisenberg).

The bacilli are best stained with a concentrated alkaline solution of methylene-blue in water. For staining the bacilli in sections of tissue containing them Löffler recommends that they be immersed in the above-mentioned solution for twelve to twenty-four hours, and then carefully treated with very dilute acetic acid, until the sections have been decolorized sufficiently to bring the bacilli into view. After this treatment they should be washed out in alcohol, and immersed in oil of cedar, which does not dissolve out the aniline colors, and is therefore to be preferred to oil of cloves in all preparations in which these colors are used for staining bacteria.

According to Cornil and Bakes, the bacilli of glanders differ from the bacilli of tuberculosis in the fact that they are not stained by Ehrlich's method, and that when stained with an aniline color they are decolorized when treated with nitric acid. Löffler first obtained cultures of the bacillus, which he had previously recognized in the characteristic nodules of an infected animal, by placing small bits of lymph-glands, spleen, liver, and lung tissue, in a variety of fluid media, and upon blood-serum of the horse and of the sheep. At the end of three days, during which time the cultures were kept in the incubator at 38° C., development had occurred in the various fluid media, and upon the jellified blood-serum, in the form of small transparent droplets, having a yellowish color. A series of pure cultures, made from this source, was subsequently tested upon various animals. Two horses, inoculated respectively with the eighth and tenth generation of the bacillus, developed unmistakable glanders; one died, and the other was killed. In both the characteristic lesions were found, and the presence of the bacillus was demonstrated in the diseased tissues and lymphatic glands, by microscopical examination, and by culture experiments.

Further experiments upon animals showed that the guinea-pig, and the field mouse, are the most easily infected by inoculations with pure cultures; that the rabbit is somewhat less susceptible; and that there are decided differences in the resisting power of different individuals. While the field mouse is extremely susceptible, the house mouse and the white mouse are almost insusceptible. The same is true of the white rat, which seems to be immune from most of the infectious diseases which have been studied experimentally. The ass and the sheep are susceptible. Among birds the pigeon alone exhibited some degree of susceptibility.

Löffler insists that in a suspected case of glanders in man, the diagnosis can be established without difficulty by a demonstration of the presence of the bacillus. This is easily accomplished by ob-

taining, with proper precautions, the contents of an unopened abscess or pustule, and planting a little of the same upon blood-serum in several test-tubes, and also upon slices of cooked potato. A number of cover-glass preparations should also be made, and stained with methylene-blue. In the course of a few days the characteristic transparent, yellowish droplets will appear upon the blood-serum, and upon the slices of potato a honey-yellow layer will be seen. From these cultures one or more mice or guinea-pigs may be inoculated, in order to confirm the diagnosis. It is not an easy matter to isolate bacilli from the nasal discharge of a suspected animal by means of the plate method. In this case it is simpler to test the question of the presence of the bacillus and the nature of the disease, by inoculating a guinea-pig. Two or three days after inoculation an abscess forms at the point of inoculation, and soon the nearest lymphatic glands become swollen. According to Flügge, when only a small quantity of material has been injected subcutaneously, the process may remain stationary for weeks; otherwise, acute nodular swellings occur in the testicles, or ovaries, upon the vulva or feet, and an ulcerative process is established in the nasal cavity.

Löffler says that infection may occur in animals through a superficial wound, or through the digestive or respiratory tract. The bacilli, apparently, cannot penetrate through the uninjured skin or mucous membrane. Numerous experiments have shown that pus from the nostrils of an animal suffering from glanders, may be introduced into the nasal cavity of a healthy horse, upon cotton wadding, or by means of a brush, without result.

An animal suffering from glanders may give birth to young which have become infected *in utero*. This has been observed in the case of the horse, and Löffler relates an interesting case in which the fact was verified by an experiment upon the guinea-pig. One of these animals was inoculated with material taken from a glanders nodule in the lung of another. A chancrous ulcer developed at the point of inoculation, the glands in the vicinity became swollen, and swelling of the left foot occurred. All of these appearances disappeared, and at the end of five months the animal gave birth to a young one, which was apparently healthy, but died four weeks after birth. A post-mortem examination demonstrated the presence of glanders nodules in the liver, the spleen, and the lungs; not, however, in great numbers. Infection after birth is excluded, from the fact that there was no external evidence of glanders. The nasal cavity was healthy, and the lymphatic glands were not swollen.

CASE OF PYELONEPHRITIS DEPENDENT UPON RENAL CALCULUS.

BY EDWARD T. BRUEN, M.D.,

I HAVE brought forward the history of the single case which forms the basis of this paper on account of its intrinsic interest from the standpoint of diagnosis, and the rare character of the specimen obtained at the post-mortem examination.

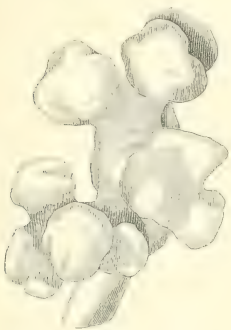
The patient, Catharine W., aet. forty, was admitted to the Philadelphia Hospital, March 24, 1886. Family history excellent; she has always enjoyed good health until eight years ago, when she first felt pain in the left lumbar region with frequent and painful micturition. These symptoms would vanish at times, but would appear at intervals. In July, eight months prior to the date of admission, she awoke one morning with a violent pain in the left side, which radiated from her back through the abdomen. It was also transmitted down the left limb, and was increased when she straightened the left leg—giving her the impression that she had hip disease. There was also some fever. After this attack she recovered sufficiently to attend to her ordinary duties, but at intervals the pain, with fever, returned, continuing for a week at a time—and the pain in the hip was often sufficient to make her desire to lie with the thigh flexed on the abdomen and the leg on the thigh.

In January of last year, three months before admission to the hospital, she had a severe attack of pain, accompanied by vomiting. From this time she progressively lost flesh and strength. When admitted, March 24, 1886, she complained of a dull aching pain in the splenic region with tenderness on palpation over the lumbar, and also left ovarian region. The most sensitive point was midway between the spine of the ilium, and along the border of the ribs. Between the lower ribs on the left side, nearly down to the crest of the ilium there was an area of dulness, which extended anteriorly to a point corresponding with a line drawn from the anterior superior spinous process of the ilium, to the edge of the ribs. The dulness did not extend downward more than three or four fingers breadth below the edge of the ribs and was masked by the intestinal resonance. She passed usually only a little over eighteen ounces of urine a day, and nearly half was pus.

Her general appearance was anæmic and nervous. The temperature was constantly above 99°, the evening temperature being 1° higher. The general condition continued unchanged during the period of three months which she passed in the ward. Death supervened through exhaustion, June 5, 1886.

The post-mortem examination was made twenty-four hours later. The body was emaciated, with but little cadaveric rigidity. On opening the abdominal cavity, the small intestine was found bound down to the uterus and fascia of the pelvis by strong adhesions. A large tumor was situated in the left lumbar region, extending from the rim of the pelvis along the psoas muscle close to the vertebræ. It was about seven inches long and three and a half broad—the upper border of the tumor corresponded with a plane drawn across the body at the tenth rib in a line with the angle of the left scapula. In the anterior axillary region a plane drawn across the body just below the tenth rib would have traversed the bulk of the tumor at its upper portion. On opening the tumor it was found to contain over thirteen ounces of pus. The sup-

purating sac represented the capsule and pelvis of the kidney, all vestiges of renal tissue having undergone cystic degeneration; the ureter was patulous down to the bladder—its walls were very much thickened. The tumor sac contained a large calculous mass which weighed fourteen drachms, and presented a branched appearance like a piece of coral, each branch doubtless representing as many renal calices. The main portion of the stone probably formed in the pelvis of the kidney, and one long branch descended in the direction of the ureter. There were also a few fragments of a similar character, but the bulk of the stone was one mass. The stone was chiefly composed of oxalate of lime, partially coated with a phosphatic deposit. The bladder was normal, as was the uterus, but both ovaries were occupied by small collections of pus. The left ovary was firmly adherent to the ureter of the same side. A cheesy mass was also discovered in the right broad ligament. The cortical portion of the right kidney was enlarged and fatty—the ureter was normal. The liver presented an anæmic and fatty appearance, weighing three pounds. The pancreas was somewhat enlarged. The case presents several suggestive features.



1. The initial pain, eight years before admission to the hospital, doubtless indicated the commencement of the process, and yet for only eight months were the symptoms sufficiently aggravating to compel her to appeal for medical assistance. While she was under observation the pain was not a prominent symptom, nor had it been in the past. It was mostly a dull sense of weight or uneasiness. She had never had pain characteristic of renal colic, nor blood in the urine. The history of this symptom of pain in this case corresponds with that of many cases of renal calculus. That is, in many instances the pain is not a sufficiently conspicuous characteristic of the condition to be a diagnostic feature. On the other hand, cases of suppurative nephritis of a tuberculous character have been reported in which the symptoms of pain and vesical irritation were so prominent as strongly to point to calculus and the tubercular character of the process could not have been established without the assistance of an examination for the tubercle bacillus.[1] The constant sense of pain and discomfort began in C. W.'s case about eight months before her admission to the hospital, and probably coincided with the commencement of suppuration. A case is reported by J. A. MacDonald,[2] in which the development of the symptoms resembles the present case so closely as to be well worthy of comparison. The appearance of the calculous mass is identical, only the process was bilateral. There were two masses of stone, one in the pelvis of each kidney. A still more remarkable feature is that in MacDonald's case the kidney substance was normal, nor was there even pyelitis. A consideration of this example supports the theory that in the case of C. W., the development of pyelitis was a late complication.

2. Since in this class of cases there is often an absence of characteristic symptoms, the diagnosis must be by exclusion, and in the present case the inferential evidence in favor of calculus was very strong. It was assumed that there had been no primary disease of the bladder. The reaction of the urine was acid—there was no deposit of vesical epithelium, nor was there pain or tenderness over the hypogastrium. On the contrary, the history of dull pain in the lumbar region, latterly with pain in the hips, with the tendency to retain the left leg flexed on the thigh, was highly significant of morbid process in the renal region. The position of the left limb was probably due to implication by pressure of branches of the lumbar plexus. The symptom is most marked in cases of perinephric abscess with implication of the psoas muscle. There had been no history of traumatism, one of the causes of renal suppuration, and the remaining antecedent of suppurative pyelonephritis, viz., tubercle, was excluded in this case by the absence of the tubercle bacilli from the pus,[3] and by the absence of any evidence of tuberculous disease in the other organs of the body.

It was therefore considered highly probable that a calculus was the primary cause of the process. The physical signs yielded by percussion and palpation, of tumor in the lumbar region, could not, of course, indicate the etiology of the suppurative process.

3. The indications for treatment in this and similar cases seem to be confined to operative interference. Internal medication cannot influence the seat of pus formation, or only to a small extent. The free drainage in the case of C. W., as in most cases of calculous pyelitis, showed that aspiration was not likely to be beneficial.

If an incision over the left renal region had been practised in the earlier stages of the process, a correct diagnosis of the condition could have been reached, and the stone removed—with or without

[1] The Med. News, Dec. 4, 1886. Case of tuberculous suppurative nephritis. Shepherd, of Montreal.

[2] Canada Med. and Surg. Journal, vol. xii.

[3] Examination kindly made by Dr. Crozier Griffith.

removal of the kidney. Unfortunately, at the time the patient came under our observation it was evident that her strength was insufficient to render operative measures justifiable.

At the post-mortem examination it was observed that the more superficial part of the tumor and the largest collection of pus presented between the tenth and eleventh ribs, just back of the posterior axillary line. The calculous mass, by filling up the lower part of the tumor, formed an obstruction which favored the accumulation of pus in an upward direction. Aspiration directly over this point would have involved the penetration of the diaphragm, so that the only point from which it would have been feasible to reach the collection of pus by aspiration would have been below the twelfth rib in an upward direction, but in carrying out this procedure the needle would have probably impinged against the stone, and the sac containing the bulk of the pus would not have been entered. Aspiration was indeed attempted in C. W.'s case as a tentative measure, and the needle was introduced as indicated, but with a negative result.

HOSPITAL NOTES.

TREATMENT OF PNEUMONIA IN THE NEW YORK HOSPITALS.

BELLEVUE HOSPITAL.

IMMEDIATELY upon admission every patient under the charge of PROF. ALFRED L. LOOMIS undergoes an examination for the extent and location of the following points:

1. The extent and location of pulmonary consolidation, and presence of complicating pleurisy.

2. The temperature and condition of the heart as indicated by its rhythm, force, and amount of muscular element in the first sound.

3. The condition of the kidneys.

When the patient is admitted during the initial shock, full doses of morphia are administered hypodermatically, and repeated with sufficient frequency to relieve pain, during the first three or four days, or until the consolidation is complete.

Every patient is placed in bed, clothed in an oil-silk, flannel-lined jacket, which is made to come close up around the neck and to extend well down on to the trunk, and is put upon a diet of milk, vichy, chicken soup, and beef-tea, the selection of food being somewhat affected by the limits of hospital dietary. This much is routine.

When consolidation is confined to a lower lobe, the cough, expectoration, and pain moderate, the temperature below 104° F., while the pulse is regular with a strong first sound of the heart, and the urine is normal, nothing further is done beyond keeping the bowels freely open by some mild cathartic, as pulv. glyc. co.

The general treatment is then purely expectant. The temperature and pulse, however, are taken every four hours and the urine examined daily.

When the temperature reaches 104° F., or more, fifteen to twenty grains of quinine are given at a single dose. If at the end of six hours no reduction of temperature is produced, twenty grains are given in divided doses within an hour. As the drug used is "hospital quinine," these doses are possibly slightly larger than would be required in general practice. When they fail to reduce temperature equal parts of quinine and antipyrin are employed, but always in combination with some form of cardiac stimulant, as alcohol or caffeine. If the temperature is not affected by the second dose its use is not continued.

Indications for stimulants are found principally in the cardiac condition. Patients with consolidation at the apex, however, and alcoholic subjects are put upon stimulants from the first.

The cardiac stimulants used are alcohol, caffeine, digitalis, and ammonia, the first two being given with about equal frequency and for prolonged effect, while the others are used more for emergencies in the later stages.

An irregular, uneven, intermittent pulse, or weak or absent first sound are indications for stimulants to be given p. r. n.

It is seldom found necessary to employ measures directed especially to the cough. When this is distressing, with little expectoration in the earlier stages, opium is employed to mitigate its severity but not to check it entirely; later in the stage of resolution opium is avoided and carbonate of ammonia given in connection with infusion of serpentaria or wild cherry.

Pain is controlled early by opium and *large hot* poultices, later by poultices alone, if possible.

The earliest indications of renal complications are met by the ethers, infusion of digitalis, and nitroglycerine.

Sleeplessness is relieved by bromide and chloral (alone in robust patients), and with the addition of cardiac stimulants in alcoholic subjects.

Œdema is treated by dry cups freely applied over the entire chest, atropia hypodermatically, whiskey and digitalis internally, and the free inhalation of oxygen.

ST. LUKE'S HOSPITAL.

The treatment of pneumonia in DR. KINNICUTT'S wards in St. Luke's Hospital, during the past five years, has been wholly an expectant one. Absolute rest in bed in a *strictly* horizontal position, not only until defervescence occurs, but for several subsequent days, is a rule which is carefully observed in his service. The patients are rarely permitted to assume a sitting posture, even for the purpose of an examination. Several instances of sudden death from heart failure, in the period immediately following defervescence, on the patient attempting to rise, have convinced him of the wisdom of a routine rule of this kind. Light flaxseed poultices or a layer of cotton-wool covered with oiled silk, applied over the affected area, have been found serviceable in promoting the comfort of the patient.

During the developing stage of the pneumonic process (the first three or four days), opium in small doses (morphine one-sixteenth to one-eighth grain given by the mouth or hypodermatically, two or three times in twenty-four hours) has proved of great service in controlling the symptoms of nervous shock which so frequently obtain at this stage of the disease, and in affording relief to the suffering of the patient. It has also seemed to combat, in a measure, the tendency to heart failure.

The employment of alcohol has been governed by the symptoms in individual cases. With the first indication of cardiac weakness, it has been the rule to institute its use in small doses and to watch carefully its effect. The pulse, the tongue, and the mental condition are accepted as guides for its continued use and for the amount to be given. Many cases have convalesced satisfactorily without its employment at any stage of the disease; again, twelve or more ounces of brandy have been given in the twenty-four hours, with marked benefit and recovery. Its use in diminished doses during the first days of convalescence has often been found advisable.

Caffeine and digitalis have been used very uniformly as heart tonics, and Dr. Kinnicutt believes with benefit. During the past several months, strophanthus, in the form of the tincture (five drops, three or four times in the twenty-four hours), has been employed with excellent results. He now prefers it to all other cardiac tonics in this disease. Antipyretics have seldom been employed.

On the temperature reaching 105°, a single small dose of antipyrine, eight to twelve grains by the rectum, has been given and repeated if necessary.

Aside from his disbelief in the necessity of the general use of antipyretics in pneumonia, Dr. Kinnicutt is convinced of the intolerance of large doses of the group of carbon compounds in this disease.

Finally, the alimentation of the patient has received very careful attention; the food has consisted of milk, in its raw state, or peptonized. The hospital records show the following satisfactory results under the above method of treatment.

Forty cases of acute lobar pneumonia were treated in the wards from December 1, 1884, to December 1, 1886. There were six deaths, 15 per cent. (excluding one which fairly should be disregarded, death occurring twelve hours after admission to hospital on the fifth day of the disease), all in complicated cases; the complications being: (1) amyloid spleen, liver, and acute nephritis; (2) chronic nephritis; (3) endocardial aneurism, mitral stenosis, chronic nephritis; (4) alcoholism; (5) urethral stricture with retention of urine; (6) uræmia and chronic nephritis. Serious complications existed in ten of the cases which recovered. Double pneumonia was present in three of these.

If the nature of the symptoms points strongly toward the development of pneumonia, although it is not yet perfectly evident, Dr. Beverley Robinson avoids the use of arterial sedatives like aconite, and prefers to order a few doses of ammonia, a small amount of opium (Dover's powder preferably), and a flaxseed poultice over the affected side. When the pneumonia can be clearly recognized by physical exploration of the lungs, moderate doses of digitalis (fl. extr. ♏j), and from two to four ounces of brandy or whiskey in the twenty-four hours, are prescribed.

A sufficient quantity of milk given regularly every hour, with an egg-nog, or beef extract, morning and evening, is allowed. Flaxseed poultices, containing a small proportion of mustard, are continued as a local application, and are renewed once every three hours. To retain their heat and moisture, they are covered externally with gutta-percha tissue or oiled silk.

If the bowels are constipated at the beginning of the attack, or subsequently, a dose of calomel is ordered (5 grs.), followed in a few hours by a saline aperient (℥ ss–℥j of Epsom salts). Whenever the patient is much prostrated, and the bowels remain torpid, a laxative enema is preferred. In cases where the bodily temperature rises above 103° Fah. in the axilla, five to ten grains of the sulphate of quinine by the mouth, every four hours, during the continuance of the period of relative hyperpyrexia, are ordered. Whenever the heart shows symptoms of failure, either by extreme frequency, weakness, or irregularity of its beats, the amount of brandy or whiskey to be given is rapidly increased, and strong, black coffee is also ordered.

In a very grave case of double pneumonia treated during the past winter, and in which a cure followed, the disease was combated during the acute stage almost entirely with brandy and black coffee, a half ounce of one or the other being given alternately every half hour. (The brandy should be old and pure.) Later, dry champagne was substituted for the brandy.

Some years ago, Kermes mineral (oxysulphuret of antimony) in a vehicle of syrup of gum with water, was frequently ordered by Dr. Robinson every two or three hours, in order to promote expectoration. Although excellent results were obtained from the use of this drug, for no sufficient reasons it was abandoned, and never since resumed.

If the heart action remains feeble during the stage of resolution, although the fever has disappeared during several days, he has found convallaria majalis an excellent substitute for digitalis. It agrees with the stomach better than the latter drug, and often acts quite as well as a heart tonic.

In the convalescent period, when the lung remains impervious to air during a considerable time, he has found repeated fly-blisters over the affected side extremely beneficial in clearing up the local intra-pulmonary condition. At the same time that blisters are applied, he orders small doses of belladonna, strychnine, and carbonate of ammonium in infusion of cinchona, repeated several times daily, so as to strengthen the heart's action, and tone up the general system. Whenever delirium is present, it is allayed with the ice-bag to the head, or by the internal use of ether (in perles), or of the bromides. Venesection for the asphyxia accompanying a dilated and over-burdened right heart, is occasionally advisable, and when performed under favorable circumstances, has been found useful. In his experience, however, the evident indications for this little operation have rarely occurred. The main source of danger in pneumonia, as a rule, seems to pertain to rapid or sudden heart failure. This accident may be prevented in many instances by the internal administration of repeated and considerable doses of black coffee and alcoholic stimulants.

MEDICAL PROGRESS.

The Iodol Treatment of Laryngeal Tuberculosis.—Lublinski is quoted as follows in the *Journal of Laryngology* for February, 1887:

Iodol is scarcely soluble in water, but is dissolved by alcohol and ether. Schmidt proposed a mixture of iodol,

1 part; alcohol, 16 parts; glycerine, 34 parts. This is, however, too weak. Lublinski has used the powder pure for laryngeal insufflation. It causes no pain or cough, and it remains a long time in contact with the surface. The author has used it in the treatment of fifteen cases of tuberculosis. He administered one insufflation daily, or, in some cases, two or three times a week. Under its influence ulceration quickly heals, the base becoming clean and granulating, dysphagia disappears, and the patient's health improves. Tannin, boric acid, lactic acid, and other applications will produce this effect, but not so rapidly as iodol, the action of which is striking. The author gives details of two cases of tuberculosis in particular, in which iodol produced rapid curative effects. In both there was extensive ulceration. The author also regards iodol as serviceable in ozæna and scrofulous rhinitis, with ulcers on the septum.

IS IODOFORM ANTISEPTIC?—The widespread employment of iodoform as an antiseptic dressing may receive a check should the conclusions arrived at by MM. Heyn and Rovsing, of Copenhagen, be confirmed. These observers have (*Fortschritte der Medicin*, 1887, No. 2) been making experiments with iodoform to test its value as an antiseptic, which they point out is so generally accepted that the surgeon does not hesitate to employ a non-sterilized spatula or to insufflate ordinary air with the powder, procedures which he would shrink from employing were it not for the belief that the iodoform can destroy the germs adhering to the one or suspended in the other. Yet as iodoform is rarely used to the exclusion of other antiseptics (as carbolic acid or mercuric chloride), there is never much opportunity, clinically, of testing its germicidal properties. Mikulicz, in 1881, tested the action of iodoform upon putrefaction, but with no definite result; and Rummo's experiments in 1883 were complicated by his use of oil of turpentine as a solvent for the iodoform. Meyer found in one case of abscess that iodoform had no effect in reducing the virulence of the pus, and in another that it had a slight action. The results of the research pursued by MM. Heyn and Rovsing surprised themselves. Acting on the theory that it is through liberation of free iodine that iodoform enjoys its germicidal reputation, they prepared solutions of iodoform in olive oil and in serum, and, having sterilized them, mixed them with culture media, and studied the effect of cultures of various bacterial organisms in these mixtures, as well as under iodoform powder alone. They also experimented on rabbits by mixing inoculation fluids with iodoform. The details of the experiments need not be reproduced here; suffice it to say that in no case did the presence of the substance interfere with the development of micro-organisms. So that they conclude that as an antiseptic its employment in surgery is valueless. But, more than this, its use is dangerous, for, as two of their experiments proved, iodoform itself may contain pathogenic micro-organisms; and even if all care be taken to purify it, yet it may become the medium of the conveyance of pathogenic germs introduced into it through the spray or spatula. We trust that these experiments, which have received such prominence, will be repeated, for, if confirmed, we can imagine that the use of iodoform (apart from any other antiseptic) would in certain circumstances be serious. It would be deplorable if in any such case the material upon which the surgeon relies to protect his patient from bacterial invasion should prove to be the means whereby such invasion occurred. The writers of the article themselves advise that before using iodoform (which is valuable as a dressing on other grounds than as an antiseptic only), it should be disinfected in sublimate solution.—*Lancet*, Feb. 12, 1887.

A DOMESTIC NIPPLE-SHIELD.—DR. FRANK HOLYOKE states in the *Boston Medical and Surgical Journal*, Feb. 24, 1887, that a patient who suffered from extremely sensitive fissured nipples, invented for herself most perfect nipple-shields, by suspending from a ribbon about the neck, two deep, wire tea-strainers. They were held in place by a properly-fitting waist, and the nipples, thus covered, were entirely free from any irritation. She had, moreover, such a copious supply of milk, that it was otherwise quite impossible to keep the nipples dry. This was remedied by the ready passage of the milk through the wire gauze to a layer of absorbent cotton covering the tea-strainer. Not until she began to employ this method of protecting the nipples did the process of healing go on satisfactorily.

This young mother's clever device has been a source of great comfort in a number of similar cases which have since then come under Holyoke's care.

TREATMENT OF CYSTITIS.—RELIQUET recommends the following: Morning and evening a general bath of tepid water. An hour after the bath the following suppository should be introduced in the rectum:

Iodoform	gr. jss.
Ext. hyoscyami	gr. j.
Ol. theobromæ	gr. xlv.

When urethral discharge exists this pill should be taken morning and night:

Terpine	gr. jss.

divided into ten pills.—*Les Nouveaux Remèdes*, February, 1887.

KNIFE WOUND OF THE LIVER; RECOVERY.—BURCKHARDT, of Stuttgart, reports in the *Centralblatt für Chirurgie*, No. 5, 1887, the following interesting case:

A laborer, aged twenty-seven, was admitted to the hospital, having received, one hour previous, while upon the street, a penetrating wound of the abdomen. The knife which inflicted this wound was of the kind used by butchers, its blade being one and a quarter inches wide and three and a half inches long.

On examination, the patient was found to have the appearances of ordinarily good health; he was conscious; pallid; pulse thready, 140; respiration costal; he complained of severe pain in the abdomen and left shoulder, and was greatly terrified. In the left mammillary line there was a sharply cut wound, one inch long, whose edges had been united with two stitches. The abdomen was somewhat distended, percussion note dulled; from the upper portion to the lower border of the fifth rib on both sides the percussion was tympanitic. The patient's clothing was plentifully blood-stained; his general condition pointed to continuing severe hemorrhage, which, in the opinion of the surgeon, made operative interference imperative. The patient was anæsthetized, and the wound enlarged; the cartilages

of the ninth and tenth ribs on the left side were clearly cut obliquely, and on following the wound inward and backward it gaped, and on pressure a considerable quantity of dark blood escaped. The abdominal walls were immediately separated at their wounded edges between five and six inches, and the loop of intestine which lay nearest the wound, and was immersed in blood, was brought out and examined for the point of hemorrhage. The location of the wound pointed to an injury to a large artery of the stomach or mesentery, rather than to an injury of the liver, as the source of bleeding. When no such arterial wound was found, the liver was examined, and an incised wound, about one and a quarter inches long, was found in the left lobe, from which dark blood was escaping, as from a cavernous angioma. The index finger penetrated the liver toward the right and posteriorly from two to two and a half inches. The collapse of the patient forbade further exploration. The liver wound was accordingly tamponed with a strip of iodoform gauze of convenient width, and about four inches of gauze were allowed to protrude from the orifice of the abdominal wound. The loop of intestine which had been handled was washed with sublimate solution, replaced, and the abdominal wound, excepting its upper angle, was closed. At this upper angle were left the protruding gauze, and a large drainage tube, which extended to the upper surface of the liver. A thick antiseptic dressing was added. The patient reacted under stimulants; the pulse became normal on the third day; the temperature rose on the second day, and continued until the eleventh, in spite of large doses of thallin, at 103° F. at evening, with corresponding pulse frequency; pulse and temperature were normal after the eleventh day.

The general condition of the patient was strikingly good in comparison: symptoms of peritonitis were wanting, and only the vicinity of the wound was somewhat sensitive.

On the fourth day, synchronous with a rise of temperature, frequent cough developed with muco-purulent blood-tinged sputum, and dulness and bronchial breathing over the lower portion of the right lung. Diarrhœa and pain about the cæcum were present for some days. Icterus was absent; bile coloring-matter was found once in the urine. The lung complication was thought to be due to non-septic embolus.

At the first dressing, on the morning after the injury, a free discharge of blood was found; the dressings remained unsoiled until the sixth day, when a muco-biliary secretion stained the gauze, which was removed, and a drainage tube alone substituted. The discharge of bile increased to six drachms daily, began to decrease on the twelfth day, and ceased on the fifth week. At the end of the fourth week the gauze was removed from the external wound, and at the end of the ninth week a fistula only remained. This persisted for several months; the patient was finally anæsthetized, the fistula dilated, and a piece of gauze was found lodged deeply in the wound; after its removal rapid healing followed. In less than nine months from the time of the receipt of the injury the patient was at his work, free from all embarrassment. If the gauze had not been left in the wound, it is the opinion of Burckhardt that the patient would have recovered in eight or nine weeks.

Treatment of Emphysema and Catarrhal Bronchitis.—Dujardin-Beaumetz recommends the following:

℞.—Potass. iodidi . . . . . ʒiv.
Aquæ . . . . . ʒviij.

Teaspoonful or tablespoonful in a glass of beer at the commencement of each meal. Also at each meal three capsules of terpinol. Baths of compressed air.—*Les Nouveaux Remèdes*, February 8, 1887.

Meat Extract in Acute Febrile Diseases.—It is plainly evident that we cannot suppose that the use of meat extract tends directly to nourish the febrile patient, because it contains neither albumen, fat, nor carbohydrates. But on account of the salts and extractive matter it does contain, the extract may, on the other hand, act as a stimulant and analeptic; and its stimulating action may prove prejudicial or beneficial according to circumstances. Wherever there is considerable irritability of the digestive tract, the administration in quantity of the extract is liable to produce flushings, palpitation, acceleration of the pulse, and still further deterioration of the appetite. When, however, there is not such condition of hyperæsthesia, and especially if the digestive functions are about to be restored, suitable quantities of the extract are not only tolerated, but are beneficial. It stimulates the appetite, and, on account of the needed salts it contains, acts as a restorative, and promotes plastic processes. The possibility of its irritant action should, however, not be forgotten.

The employment of meat extracts at the beginning of acute disease is at least to no purpose. If, however, at any time, symptoms appear rendering rapid stimulation necessary, as in aged persons (and in them possibly early in the attack), in febrile conditions following great loss of blood, in relapses, and in long-continued fever, when the nervous system, exhausted by the increased blood heat, sleeplessness, and deficient nutrition, requires a stimulant to enable it to continue its functions until the decline of the disease—in those conditions, as well as in cases of sudden prostration, a teaspoonful in warm water, or added to broth, administered several times daily, often proves to be of great utility. What has been said respecting meat extracts, applies to ordinary beef broth, though in certain respects in a less degree, inasmuch as the latter contains a proportion of gelatine and albuminous matter. The administration of meat broths, rendered still richer in albumen by the action of hydrochloric acid, or yolk of egg, is appropriate when a stimulating action is desirable, and when the condition of the digestion is such that nourishment of this kind is likely to be digested. In severe collapse their use is bootless, as absorption and assimilation are then nearly always extinguished.—*Journal of Dietetics*, January, 1887.

Hypodermatic Injection of Atropine in Hæmoptysis.—Hausmann advises this method of treatment in desperate cases of hæmoptysis when the use of other remedies has failed. He reports three cases which illustrate this point. One case had suffered from twelve severe hemorrhages in six hours. After the thirteenth the writer injected one-twenty-fifth of a grain of sulphate of atropine; the hemorrhage did not recur. A

similar result was obtained with a lady, in whose case ergotine and preparations of turpentine had failed.

In a third case of persistent hemorrhage through two winters, two injections, of one-twenty-fifth of a grain each, subcutaneously, check them.—*Revista Clinica, Therapeutica*, February 15, 1887.

ANTIPYRIN IN PHTHISIS.—Antipyrin has been shown to have various uses, but if the success which has been reported by Dr. Zakrzhevski in a paper contributed to the *Russian Military Medical Journal* attends the practice of other medical men, this drug will hereafter be looked upon as almost a specific. While under ordinary methods of treatment the mortality of phthisical patients in the Helsingfors Hospital was 50 per cent., during the eight months in which the antipyrin treatment has been carried out not a single case has proved fatal, many of the patients having, on the contrary, improved so decidedly as to be able to return to their homes. The author much prefers the hypodermatic method of administering antipyrin, as the effect is produced in less than an hour, whereas when the drug is given by the mouth no effect is produced for from one to three hours. The action of antipyrin is to increase the force of the cardiac contractions, and so to raise the blood-pressure. In phthisical patients it slows the pulse, but never quite to the normal rate. It also slows and deepens the respirations, and the digestive functions are improved. No albuminuria or other sign of renal disturbance was observed. With regard to the dose Dr. Zahrzhevski finds that it should be regulated by the strength of the patients. In a man with phthisis, who was still fairly robust, a full dose of ninety grains was required in order to produce the best effect; whereas, in greatly debilitated typhus patients ten or fifteen grains were quite sufficient, and in cases where there was decided exhaustion it was found that a dose of sixteen or seventeen grains was the largest that it was advisable to give.—*Lancet*, February 5, 1887.

AN INJECTING FLUID FOR ANATOMISTS.—IMADA, Professor in the Imperial Medical College, of Japan, has obtained good results with the following fluid in injecting cadavera: The following are the proportions for one body:

[illegible]	℥xx.
[illegible]	℥xx.

Mix thoroughly, and add the following prepared as directed:

Wheat flour	℥j
Vermilion	℥ss to ℥j.

Mix these articles in a dry state, triturate together, and add water, ℥ij.

After injecting this mass an injection of solution of carbolic acid should be made to prevent putrefaction. The following has been found useful:

[illegible]	℥ss
Glycerin	℥ss
Aquæ	℥ss

—*Journal of Anatomy and Physiology*, 1887.

ON INTUBATION OF THE LARYNX.—The *Journal of Laryngology* for February, 1887, contains the following regarding BOUCHUT'S early conclusions concerning intubation.

Referring to recent literature, Dr. Bouchut relates the fact that nearly twenty years ago he, being then struck with the terrible inefficiency of tracheotomy, sought some means of replacing this operation, and read at the Academy of Medicine (in 1858) a memoir "On a New Method of Treating Croup by Tubage of the Larynx." He there sought to prove that it was easy to practise tubage of the larynx by means of a canula fixed on the vocal cords and not interfering with the functions of the epiglottis. He added that it was possible to remedy in this manner the asphyxia of croup and other affections of the larynx, and that this method was to be preferred to tracheotomy. Trousseau then formulated this conclusion—tubage cannot replace tracheotomy except in rare instances, and this is the principal means of dealing with croups in which other medical treatment has failed. Bouchut's communication was treated curiously as an unpatriotic attempt to depreciate a method of treatment "entirely French," and the discussion which followed took the character of a veritable "execution." Recent publications have proved that the Academy was wrong, and that Bouchut was right.

HEROIC DOSE OF TURPENTINE IN CROUP.—In an obstinate and dangerous case of diphtheritic croup, which had extended into the larynx, after painting with boracic acid, and subsequently with a chloric acid application, without benefit, the child's condition becoming worse and worse, DR. LEWENTANER, of Constantinople, before resorting to tracheotomy, remembering a paper by Demlow in which turpentine was recommended in these cases, determined to give it a trial, and so administered with his own hands a teaspoonful of the pure oleum terebinthæ, giving after it some warm milk. In a quarter of an hour the labored laryngeal breathing had given way to normal respiration sounds. That night the child slept well and was quite free from the brassy cough which had previously been present. The next morning he was quite lively and was found playing with his toys. All trace of false membrane had disappeared from the pharynx, which merely presented a reddened surface. Convalescence was rapid and uninterrupted. The turpentine, however, caused an eruption on the face, trunk, and extremities, having much the same appearance as the rash of measles, but of a brighter red. The spots completely faded in two days, and were followed by no sign of desquamation.—*Lancet*, February 5, 1887.

ANTIFEBRIN IN THE ROYAL INFIRMARY, EDINBURGH.—Antifebrin has now been employed for several months in the Royal Infirmary, Edinburgh. It was used by Prof. Grainger Stewart shortly after the first account of its properties was published, and since then it has been largely used in more than one ward. The antipyretic qualities of the acetanilide have been most thoroughly tested, and it now occupies a high place among the febrifuge resources of the Infirmary. More especially it has proved superior to antipyrin, kairin, and thallin, in its freedom from accompanying disadvantages, such as the production of vomiting, rigors, and other discomfort, at the various stages of its action.—*British Medical Journal*, February 12, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

PHILADELPHIA.

SATURDAY, MARCH 12, 1887.

THE PROGNOSIS IN CHRONIC VALVULAR DISEASES OF THE HEART.

AT the last meeting of the British Medical Association there was a discussion on this subject, elicited by a remarkable report of SIR ANDREW CLARK on "Cases of valvular disease of the heart known to have existed for over five years without causing serious symptoms," which appeared in the *British Medical Journal* for February 5th, 12th, and 19th. From his case books, in private practice, between the years 1873 and 1886 he has extracted and tabulated 683 cases in which there existed chronic valvular disease, the presence of which was not indicated by symptoms, and did not sensibly interfere with health. In selecting these cases, it is distinctly stated that there were excluded all instances of mere murmurishness, all inconstant and intermittent murmurs, all which were doubtfully endocardial, all in the pulmonary and tricuspid areas, and all cases which, independently of cardiac examination, had subjective or objective symptoms of heart disease.

These 683 persons consulted Sir Andrew Clark for various affections unconnected with the heart lesions; thus 326 were suffering from disorders of the digestive system; 134 had disorders of the nervous system; 61 had rheumatic affections; 47 were suffering from disorders of the respiratory system; 30 from affections of the skin, and 23 had gout. Elaborate tables state the age, sex, valve affected, character of the murmur, probable cause, duration, habits of life, general health, and other points of interest.

He then proceeds to discuss the histories, habits, environment, and general condition of these patients in order to discover to what circumstances they owed immunity from the secondary consequences of valvular disease. As conditions which favor this, he gives, "a simple, regular, occupied, and moderately active life, early hours, a tranquil mind, disciplined control of the emotions and will; regular, but neither too frequent nor too full, supplies of fresh nourishing food; extreme moderation in the use of tea, coffee, and alcohol; avoidance of sudden and violent forms of exertion, of hurry and worry, of prolonged tension of mind and of serious and depressing cares and fears." Of circumstances which promote the consequences of valve disease, some act directly upon the heart, others on the general health. Chief among them are "irregularity of life, excesses and irregularities of eating and drinking, the too generous use of alcoholic beverages, the intemperate use of liquids in themselves harmless, the abuse of tea, coffee, and tobacco, excessive and insufficient exercise, anxious introspection and self-distrust, undisciplined emotions, prolonged and serious cares, inattention to the secretory functions of the body, and a sedentary, self-indulgent life." In a given case of valve disease, for example, mitral regurgitation, Sir Andrew Clark holds that the following conditions would justify the physician in permitting him to continue at his ordinary work, sustain an application for life assurance, or sanction marriage: good general health, and just habits of living; no special liability to catarrhal or rheumatic affections, the origin of the valve lesion independently of degeneration, the existence of the valve lesion without change for over three years, sound ventricles of regular action, sound arteries, free course of blood through the cervical veins, and freedom from pulmonary, hepatic, and renal congestion. Ten or twelve very interesting illustrative cases are given of persons living long and useful lives after the discovery by the physician of, what appeared at the time, serious heart disease.

Among the conclusions based on an analysis of these cases, the following will command the attention of those interested in examinations of the heart: That there are many persons with long-standing valvular disease engaged in the active business of life, who, without any symptom of heart disorder, have enjoyed good health and have reached an advanced age; that the mitral regurgitant murmurs so often encountered in chorea, for the most part, disappear within eight or nine years after the attack; that valvular inflammations and their effects arising in the course of rheumatic fever do sometimes disappear and leave behind no clinical evidence of their former existence, and that this occurring for the most part in the young, also occurs sometimes in the middle-aged; that the signs of valvular defects arising out of the degenerative changes of middle life do also, on rare occasions,

disappear, and that, when circulatory and respiratory disturbances accompany their commencement, they sometimes subside, and permit of apparently complete readjustment.

To certain other points in this report, and in the discussion, we shall again refer, as the matter is one of special interest to every practising physician.

NEPHROLITHOTOMY.

IN a recent interesting discussion at the Clinical Society of London, recorded in the *Lancet* of February 19th, KNOWSLEY THORNTON reported seven cases of nephrolithotomy, three by the lumbar incision, with one death, and four by the combined ventral and lumbar incision, also with one death; the fatal result in both instances being due to suppression of urine. In his remarks he condemned the lumbar operation, and asserted that the combined operation was the proper one for the following reasons: That the affected kidney would always be found; a healthy one would never be cut into, and the one with the stone be left untouched; that the peritoneum would never be damaged without knowing it; that both kidneys and ureters could be examined through the ventral wound; and, finally, that, through such an examination, a decision could be reached as to whether nephrotomy or nephrectomy was the proper operation in each individual case.

In support of the first two objections to lumbar nephrolithotomy, a case was narrated which pointed to left renal calculus, but in which, by the combined incision, five calculi were removed from the right organ. The third objection, that the peritoneum might be opened through the loin, while among the possibilities, has no foundation in fact; while the fourth and fifth advantages in favor of the combined incision are partly true and partly assumed. As just pointed out, symptoms referable to one side might be present when the calculus was on the opposite side, and there can be no question that an exact diagnosis is essential to success. Palpation of the kidney through the abdomen, it must, however, be stated, may fail to detect the concretion; and, as Thomas Smith stated in the discussion, cases have occurred "in which the most careful palpation of the kidney, and even pressing it against a solid table, was unable to diagnosticate the presence of a stone in the removed organ."

While some of the objections to lumbar nephrolithotomy hold good, we take it that surgeons in general will scarcely be induced to relinquish the safer for the graver procedure, the latter of which has, moreover, the decided disadvantage of exposing the patient to the risk of ventral hernia. Up to the present date, 36 lumbar incisions have afforded 4 deaths, or a mortality of 11 per cent., while Thornton's 4 combined lumbar and ventral operations show 1 death, or a mortality of 25 per cent.

PAROXYSMAL CARDIAC DYSPNŒA.

ASTHMA, literally *panting*, occurs when the air or the blood enters the lungs with difficulty. Cardiac asthma, or dyspnœa as it is now more frequently called, is one of the most constant and troublesome symptoms of heart disease, and may be continuous or paroxysmal. With failure of compensation in valvular disease, a more or less continuous dyspnœa develops, and usually prior to this period there are occasional attacks of shortness of breath, induced by exertion, or flatulence.

In this number of THE NEWS, DR. LOOMIS calls attention to the more serious form of paroxysmal cardiac dyspnœa, commonly associated with myocardial rather than valvular changes, and which may prove suddenly fatal. Scarcely sufficient stress is laid upon the frequency of the occurrence of these attacks by systematic writers on the heart, and the cases reported by Dr. Loomis form a valuable contribution to our knowledge of the conditions under which they occur.

The most constant lesion is degeneration and thinning of the cardiac walls, more advanced on the right than on the left side. Often, too, the coronary arteries are occluded. The primary or predisposing cause is a gradual failure in the organic power of the heart, and "the exciting cause of the paroxysm is anything which will lead the heart-failure to an entire suspension of the cardiac circulation." In the majority of instances Dr. Loomis holds that the arrest is in the right heart, and in this agrees with Bramwell, who, in his too short description of this form of dyspnœa, ascribes it to sudden distention of the right ventricle and imperfect supply of blood to the lungs. It is a matter of common observation that these attacks are particularly apt to occur in the early morning, and patients will awake from a sound sleep in a paroxysm of most distressing dyspnœa, which may, indeed, as in two of the instances referred to in the paper, prove fatal.

THE TREATMENT OF THE THIRD STAGE OF LABOR.

EXPERIMENTS, conducted lately in some of the large lying-in hospitals of Germany, to determine the relative merits of the expectant or Ahlfeld's treatment of the third stage of labor, and of the expression of the placenta according to Crede's method, have seemed to demonstrate the superiority of the latter plan of treatment. AHLFELD, however, in the *Centralblatt für Gynäkologie*, claims that his method has not been fairly treated, and explains again that his plan is to leave the uterus untouched for an hour

and a half after the birth of the child, and then, if the placenta has not been already expelled, to express it, while the well-known method of Credé, on the other hand, consists in expressing the placenta during one of the first two or three pains after the birth of the child.

The lesson to be learned by the practical physician from this discussion, is that here, as in so many other instances, his safest course lies in *medias res*. While it is usually unnecessary to express the placenta the minute the child is born, it is still less desirable to allow the woman to lie half delivered, in what has been happily called the squalor of labor, for an hour and a half. If a choice is to be made between these two methods, it will certainly incline more toward that of Credé than that of Ahlfeld.

QUACK ADVERTISEMENTS IN RELIGIOUS JOURNALS.

Medicine has no quarrel with theology. The physician and the religious teacher have their respective spheres, and neither conflicts with the other. Once, indeed, their functions were united, and he who cared for the soul also had charge of the body; but the separation of the offices has been a necessary result of the progress of knowledge. While each has his respective duties, they can often be mutually helpful, and any alienation between them is to be deprecated. Yet how often is occasion given for such antagonism, by clerical endorsement of quacks and of quackery! It is right, however, that we should here say that many years' observation has led us to believe that it is much rarer to find a Roman Catholic priest supporting irregular systems of medicine, or recommending nostrums, than it is to find a Protestant clergyman doing so. We believe this statement will be confirmed by others, no matter how it may be explained.

It is proper, too, that attention should be called to the readiness with which quack advertisements are admitted into religious journals. We have before us a weekly publication of one of the most intelligent and strongest Protestant denominations, and in this journal, which is doubtless read by thousands throughout the United States, there are between fifteen and twenty quack advertisements. Some of them are deceptively inserted with reading matter, as if part of it; thus "almost miraculous" cures by a drug, which most physicians know to have very slight therapeutic power, precedes a news item, and that item is followed by the advertisement of a "syrup" for teething children which depends chiefly for its power upon opium, a remedy which should not be employed without a physician's advice; it is stated that this medicine "softens the gums," an assertion which any man of sufficient intelligence to conduct a religious journal ought to know is a lie. Then follows a statement in regard to a remedy for consumption, "thousands of hopeless cases have been permanently cured," and this every intelligent man and woman in the land knows is false, yet there are hundreds of the poor victims of the disease, who are thus tempted into spending their last dollar to secure such a sovereign remedy. Then there is another preparation, a small particle of which is placed in each nostril, which, among other marvellous results, cures "hay-fever." We find, too, that some one advertises a certain cure for "even the worst cases of epilepsy," another who, to the disgrace of the clerical profession, or as a trick to catch the unwary, puts "Reverend" before his name, promises to cure any case of catarrh or bronchitis, "no matter how desperate," and then, as if to complete a triad of falsehoods, these two advertisements are followed by one in which "a positive and speedy cure" of goitre is promised.

But we desist from the sickening review of this prostitution of the religious press to falsehood and fraud. No matter how earnestly and eloquently a journal may plead for honesty and truth, if its advertising pages are occupied by such mischievous statements, its influence for good is sadly weakened. The editor, we will suppose, says "Let us pray," and some of the advertisers respond, "Let us prey," and he lets them! A clean religious journal, one from which all quack advertisements are excluded, is sadly needed, and the need ought not to continue long.

At a recent meeting of the New York Surgical Society, Dr. R. F. Weir read a valuable paper on "Four Months' Operative Work at the New York Hospital," which may be found in the last and present numbers of The Medical News.

Our object in calling attention to these articles is to commend the plan originated by Dr. Weir, and to express the hope that it may be imitated by other hospital surgeons. If it be generally adopted, an important collection of facts will be added to our common stock of knowledge; it should be distinctly borne in mind, however, that the true value of such contributions will depend upon accurate reports of minute details of individual cases—details which must embrace the symptomatology from the outset—as well as the manual procedures adopted when they vary from the ordinary methods. In such reports, too, nothing should be concealed. If a sponge or two be left behind in a wound, as happened in an operation for evacuating a perinephritic abscess, recorded by Weir, or other mishap be met with, it must be candidly stated. We are all fallible; accidents happen to the best of operators; and their reputation is rather enhanced than hurt by the open confession of their faults.

At a recent meeting of the *Société de Thérapeutique*, there was a discussion on the value of liquid vaseline, introduced by Meunier, of Lyons, as a medium for the hypodermatic injection of such irritating bodies as iodoform, iodol, thymol, menthol, etc., which are very apt to produce abscess. Meunier's formula has already been published in THE NEWS of February 26th. DUJARDIN-BEAUMETZ stated that he had found this plan very advantageous, particularly in using eucalyptol and iodoform. The injection is not painful, and it does not cause local trouble.

THE remarkable results which have followed operative interference in diseases of the bile passages are illustrated by the reports in THE NEWS of February 19th and 26th, of two cases by OHAGE, of St. Paul, to whom is due the credit of having been the first in this country to perform cholecystectomy. At a recent meeting of the Berliner Medicinische Gesellschaft, January 26th, LANGENBUCH, who devised the operation, stated that he had operated in twelve cases, of which two had died. This makes the total number of cases sixteen, with a mortality of two, a very much lower mortality than in cholecystotomy.

IN the Sundry Civil Appropriation Bill, Congress has granted an appropriation of $10,000 toward defraying the expenses incident to the meeting of the International Medical Congress at Washington this autumn. $35,000 was the amount asked for.

MR. J. S. MORGAN, the well-known American banker in London, has promised the munificent sum of £10,000 in aid of the funds of Guy's Hospital, on condition that the £100,000 required to put the institution into a state of thorough efficiency be secured by May 1st.

An Act to prevent traffic in impure and unwholesome milk, providing for the appointment of inspectors, and establishing penalties for infringements of the rigidly defined conditions governing the sale of milk, is now under consideration by the Pennsylvania Legislature.

Milk exposed to emanations or exhalations from the discharges or bodies of persons affected with any contagious disease, or milk from cows in a crowded or other unhealthy condition, or fed upon distillery waste, or any putrefying substance, is excluded from sale, together with milk in every phase of dilution and adulteration. The bill is defective in not defining the maximum quantity of water which may be present in milk without dilution, and in not making direct provision by which inspectors may be empowered to visit the dairies, but, despite these omissions, its tendency is good and the interests of the public demand that it should speedily become a law.

THE President failed to sign, before the adjournment of Congress, the Act to establish the order of promotion in the Medical Department of the Army, of which we gave an abstract in our issue of February 26th, and hence it falls.

THE University of the City of New York on Tuesday conferred the degree of M.D. on one hundred and fifty-one graduates.

THE Long Island College Hospital held its twenty-eighth annual commencement last week, and President Hutchison conferred the degree of M.D. on thirty candidates.

AN Act before the Legislature of New York calls for the revising and codifying of the multifarious laws that now stand upon the statute-books for the regulation of the medical profession. There are not far from twenty different acts, beginning with that passed in 1806, relating to the licensing and registration of the profession. As might be expected, there is no agreement or harmony between these laws, and even medical lawyers are befogged by their incompatibilities and contradictions. The time has come when a carefully considered codifying act will be useful, and it is practicable now to pass such an act; and the one above referred to would appear to be such, from the fact that it was framed by the legal adviser of the New York County Medical Society, who has had a vast experience in the courts in the prosecution of fraudulent practitioners, and in otherwise getting at the purport and intent of the laws. The proposed law aims to procure a registration of physicians who can present a good and sufficient form of credentials, and to reject those who cannot.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 5, 1887.

THE VICE-PRESIDENT, CHARLES CARROLL LEE, M.D., IN THE CHAIR.

DR. WILLIAM H. THOMSON read a paper on the

PATHOLOGY AND TREATMENT OF EPILEPSY, BASED ON NOTES OF SIXTY CONSECUTIVE CASES IN PRIVATE PRACTICE.

He related the case of a gentleman who was subject to sudden and transitory attacks of aphasia, always without any loss of consciousness whatever, and without the slightest sign of motor disturbance of any kind. The phenomena of an epileptic fit are usually described as consisting, first, of an initial aura; second, loss of consciousness; and, third, convulsions; but, not-

withstanding the prevalent opinion as to the essential clinical characters of the disease, he believed this case to be one of true epilepsy.

He then proceeded to inquire what the essential and invariable element in epilepsy really is, and expressed his conviction that it is *suddenness*. Epilepsy, he said, is the single truly sudden disease. The only affections which resemble it in this particular are laryngismus stridulus and spasmodic asthma; but in them the suddenness of the attack is not absolute, as in epilepsy. Apoplexy, hemiplegia, and sunstroke cannot be strictly compared with it, as they are in reality accidents, and more or less permanent in character. The attacks of hysteria and of neuralgia are not nearly so sudden as those of epilepsy. Other affections are more or less progressive in their onset. The only apparent exception is angina pectoris; but this affection acts on the principle of shock. All recurring symptoms coming on suddenly, such as nausea, visceral disturbances, headache, etc., are ominous, as they may perhaps be the beginning of epilepsy. The importance of this element of suddenness, he thought, could not be overrated.

The *petit mal* he considered the most real, as well as the most objectionable kind of epilepsy. He then referred to the cell discharge or explosive theory of epilepsy, and quoted Hughlings Jackson in regard to it. The exhaustion of the cells of the sensorium, he thought, was the result of the discharge which had taken place. In this connection Dr. Thomson referred to Nothnagel's "convulsive centre," and said that if no form of epilepsy except the *petit mal* had ever been observed, he felt certain that the explosive theory would never have been proposed. In answer to the views of Jackson and Gowers, he would state that in every convulsive seizure a motor discharge is granted, but to say that the first event in epilepsy is a motor discharge is a very different matter. All motor phenomena except the voluntary, he believed, are under the control of sensory impulse, and a sudden suspension of the regulating sensory impression may result from various causes. Any irregular motor phenomena are, therefore, due to a loss of the customary sensory influence. This explains the clinical facts of epilepsy without the necessity of supposing any additional nervous force being called into action. It is comparable to the jar imparted to an ocean steamer when the propeller is lifted by the height of a wave out of the water; the customary resistance of the latter being temporarily withdrawn, but no additional power being imparted to the screw.

He then referred to pleuritic epilepsy, which has been known to result from the injection into the pleural cavity of weak solutions of iodine, carbolic acid, etc. In cases of this kind the face became pale, inspiration was suspended, and the pulse could be scarcely felt. Spasms, at first confined to one side of the face, afterward became general, and finally there was epileptic coma. In a number of cases death had resulted; but no lesion of the brain was discoverable at the autopsy. The effects here produced were certainly not due to the therapeutic agent employed, but were the result of a quite unusual impression on the nerves of a cavity wholly unaccustomed to this kind of an irritation. Of a similar character were the experiments of Brown-Séquard, who found that in guinea-pigs and some other animals, section of the spinal cord, or even of one or both sciatic nerves, was followed by well-marked epileptiform fits, which returned again and again, and could at any time be excited by slight irritation of the cheek or of the side of the neck.

Dr. Thomson considered the phenomena of epilepsy to be due to the effect of an afferent sensory impression, when there is some abnormal condition of the cells of the nerve centres. What this condition is, he was not prepared to say with any positiveness, but it seemed probable to him that it is one of malnutrition. It might be asked if he would assert that all cases of epilepsy are attended with sensory impressions, in the face of the well-known fact that in certain instances there were definite lesions of the brain present. The answer was, that we do not get rid of the sensory element when we enter the cranial cavity. There is a sensory as well as a motor aphasia. A syphilitic gumma of the brain may be as true an excitant of sensory irritability as an external influence; and the same is true of any source of irritation in the brain. He did not hesitate to acknowledge that a motor centre could be excited by the application of an electric current after trephining the skull; but the explanation of the phenomena noted he believed to be in the fact of a wholly unaccustomed irritation in a centre accustomed to act in response to sensory impressions. The hypothesis of a sudden impression of sensory functions, he believed, most fully explained all the phenomena of epilepsy.

Ever since he had become satisfied in his own mind that the lesion of epilepsy is to be found in the sensory, rather than the motor centres, Dr. Thomson said he had conducted his treatment in accordance with this view, and as a result he had grown less sceptical than formerly of the advantages of treatment in this disease. The first thing that he aims at is the improvement of nerve-nutrition, and by far the best agent for this purpose at our command is cod-liver oil. It increases the number of blood-corpuscles more rapidly than iron, and has a greater effect upon nutrition than any other remedy. It is particularly indicated in malnutrition of the nervous system, because the nerve-texture is normally richer in blood-fat than any other tissue of the body. Hence it is to be regarded as the great prophylactic in all neurotic families. In epilepsy he never fails to prescribe it as regularly as he does in phthisis. Another advantage that it has is, that it counteracts in a very successful manner the debilitating effects of the bromides. Phosphorus he had also found of much service in improving nerve-nutrition, and he usually employed it in the form of the officinal syrup of the hypophosphites, with the addition of one-fifth part dilute phosphoric acid. An important part of the treatment he considered the total exclusion of all butcher meat for a period of two years; though poultry and fish are permissible. Animal diet he believed predisposes to convulsions in direct proportion to the quantity in which it is used. The tendency to convulsions in the carnivorous animals, and the absence of this in herbivorous, is due, in his opinion, to the respective diet of each class. Another thing to be avoided, is eating fast, as the too rapid mastication and swallowing of food seem to act directly on the convulsive centre of the medulla

oblongata. It is possible that the habit of eating too fast might thus induce confirmed epilepsy.

Like all other physicians, he had come to place great reliance on the use of the bromides, which so successfully control peripheric irritation. If any one doubted this, let him give thirty grains of bromide of potassium to a patient with an intolerant throat in whose case he wished to make a laryngeal examination. In the long-continued use of the remedy the great thing is to control the effects of bromism.

Dr. Thomson had found that in forty per cent. of the cases observed by him there was persistent cortical irritation, as indicated by muscular twitching during sleep, and in this class of cases he is in the habit of employing, in addition to the bromides, the bichloride of mercury, perhaps alternating it occasionally with oleate of mercury by inunction. This mercurial treatment he finds a very useful adjuvant to the bromides.

He uses belladonna or zinc oxide in all cases in which the attacks show any connection with disturbances in the alimentary canal. In this connection he remarked that bad breath is often a prodrome, and that he uses turpentine freely when there is gastro-intestinal irritation. When there is reflex irritability he uses chloral hydrate or Hoffmann's anodyne in addition to the bromides. Digitalis he employs in all cases characterized by vascular disturbance, or where there is an involuntary discharge of urine during the epileptic attack. The published experience of Dr. Newington, who found that hot mustard baths are very useful in acute mania by cutting short the attack, and inducing sleep, has led him to employ a red pepper pack at night (one drachm of capsicum being used to the pint of hot water for this purpose), in a certain proportion of cases. In one instance, at his college clinic, a patient, who ordinarily had two epileptic attacks a day, did not have a single one for some weeks after this measure was resorted to, the disease being completely arrested by the peripheral excitation thus secured. These points show, he thinks, the direction in which efforts should be made by which better results might be expected in the future, and thus relieve the treatment of epilepsy from the grievous burden of empiricism which it has so long borne.

DR. L. PUTZEL said that from a clinical point of view he did not think that Dr. Thomson's assertion that the attack is always sudden could be maintained. It is a well-established fact that there are a certain proportion of cases in which there are prodromata, often lasting for two or three days, or longer, such as digestive or mental disturbances. In regard to Hughlings Jackson's views, if he remembered them rightly, that authority simply claimed that there is an explosive discharge of nerve-cells in epilepsy, but did not imply that this discharge is from the motor cells especially. In fact, Dr. Putzel could not see how, in view of his well-known opinions upon this disease, he could confine the phenomenon to the motor cells, since he claimed that such conditions as hemicrania, for instance, belonged to epilepsy. Furthermore, he held that one aura, which may be purely mental, may, at times, constitute the whole attack.

Dr. Putzel thought that in *petit mal* paralytic symptoms are very rare. Paralytic trouble, in his experience, is usually met with after prolonged convulsions, and occurs as the result of the exhaustion incident thereto. Besides, he could not understand how the sensory impulse inhibits the motor, as stated by Dr. Thomson. In regard to so-called pleuritic epilepsy, it is not proved that the convulsions in the cases referred to were epileptic. They might, perhaps, be epileptiform, but unless a convulsive habit is established, they could not, in his opinion, be said to constitute true epilepsy. In the same way, he did not think that the convulsions of children in teething, the attack being merely the result of a temporary local irritation, could be called epilepsy; although they are often epileptiform in character. Belladonna he had used principally in nocturnal epilepsy, and in conjunction with the bromides. He agreed with Dr. Thomson, that epilepsy is a disease of impaired nutrition, and that cod-liver oil is often, therefore, of very great benefit in the treatment.

DR. MARY PUTNAM JACOBI made a few remarks, in the course of which she alluded to the confirmation of Dr. Thomson's views in regard to the danger of eating fast afforded by Lauder Brunton, who had also noticed the effect of rapid mastication in exciting the already excited centres of the medulla. As to the location of the origin of epileptic attacks in the brain, Gowers had found that one-fifth of all auras consisted of auras of the special senses.

DR. WM. H. DRAPER said that, as regards the pathology of epilepsy, the author of this paper did not seem to have thrown much light upon that obscure subject. He had confounded with the disease convulsive affections, which he did not think could be at all regarded as epileptic. As Dr. Putzel had remarked, he had spoken of convulsions produced by a variety of peripheral irritations as if they were true epilepsy, and in this opinion he could not agree. In infants and others we so often meet with conditions in which convulsions are so easily induced and which so readily disappear under treatment adapted to remove the source of irritation and improve nutrition, that he did not think that these temporary conditions could be properly compared with that grave affection which we call epilepsy.

In regard to the management, he said he agreed with Dr. Thomson as to the treatment of the impaired nutrition which was so common by cod-liver oil and tonics. In addition to improving the general nutrition, it is necessary to study very carefully the peripheral irritation which provokes the attack. In a large number of cases this is to be met with in the gastro-intestinal tract. He could not say that he agreed with Dr. Thomson as to the danger of animal food in epilepsy. On the contrary, he was inclined to think that the origination of an attack is much more likely to follow the too free ingestion of starchy food and sweets, or of the fermented liquors. He had, therefore, preferred to have his patients use principally animal food and milk, and take a diminished quantity of the carbo-hydrates; and very good results had followed the adoption of this plan of diet.

The next most important thing is the administration of some drug having the effect of diminishing the extreme excitability of the nervous centres, which is always the essential prerequisite of an attack of epilepsy. For this purpose there is nothing, in his opinion, to equal the bromide of potassium. These were all the elements of a rational treatment of this disease, and

yet he presumed that it was the experience of every physician present that there are certain cases in which all the measures referred to are of little value. Bromide of potassium sometimes signally fails unless pushed to the point of producing profound bromism; so that patients would rather have their fits at regular intervals than endure the wretched hebetude which the drug induces.

Dr. E. Darwin Hudson, Jr., said that his idea of epilepsy was, that in it there is a disturbance of the equilibrium of the nervous centres. The attack is characterized, in the first place, by a withdrawal of mental control and unconsciousness. He had met with but one case of convulsions in which consciousness was retained. They were epileptiform in character, and ended fatally, and even here consciousness was lost some time before death. In epilepsy he believed there was cerebral anæmia, and an explosion due to disturbance of the vascular equilibrium. From a clinical standpoint, it is often difficult to say what constitutes epileptiform attacks, and what true epilepsy. Successive seizures produced by peripheral irritation, not infrequently seem eventually to result in epilepsy, if they are allowed to go on without interference. He agreed with the other speakers, that the bromides constitute the most reliable medicinal means of treatment.

Dr. Thomson said that he did not intend to imply that epileptic attacks have no prodromata. On the contrary, it was extremely common in his experience to meet with patients who were almost always aware of the imminence of the attack. But a prodroma is not the attack itself, and it was this that he particularly referred to when speaking of the suddenness of the affection. He had studied this matter very carefully, and his conclusion was that epilepsy is to be distinguished from all other diseases by its suddenness. In regard to Hughlings Jackson's views, he said that he never understood his statement as referring *only* to motor discharges; but it certainly was a fact that he especially dwelt upon the explosion of motor cells. Instead of regarding sensory impulses as being of a stimulating character, Dr. Thomson said he was inclined to look upon these as a regulating force. Hence the study of the connection between any motor disturbance and the antecedent sensory impression, seemed to him of importance, as indicating the direction in which advances in our knowledge of epilepsy are to be looked for.

In regard to his confounding all sorts of convulsions with epilepsy, he remarked that Dr. Putzel, and others who had spoken, did not regard the convulsions of dentition as of an epileptic character; but he had compared these attacks very carefully with those of acknowledged epilepsy, and he had been entirely unable to discover any difference whatever between the two. First births, and especially when the children are males, he went on to say, give a larger percentage of cases of epilepsy than subsequent ones, on account of the greater compression of the brain to which the infants are subjected during the process of parturition. He then related a case of his own, in which, on account of a contracted pelvis, there was great delay in the delivery of the child, and after it was born he had been obliged to use oxygen gas for three hours, in order to resuscitate it, and when it was nine months old the child began to have convulsions, and these continued from time to time until its death, at the age of seven years. It was never able to walk. He studied the attacks in this case with great care, to see if there was any difference between them and the ordinary convulsions of children from dentition, and he became convinced that a more mythical distinction could not exist. It was simply a distinction without a difference. Here was exactly the same class of phenomena, and he would, therefore, be exceedingly obliged to Dr. Putzel and Dr. Draper if they would point out to him in what particular an epileptiform convulsion is different from an epileptic convulsion. As to the pleuritic cases which he had mentioned, if they were not epilepsy, what was the affection from which the patients suffered?

Dr. Draper replied that in saying that convulsions were epileptiform, he implied simply that they had the form of epilepsy, but not the substance. He thought there is a great difference between these temporary seizures and the regular recurrence of seizures in true epilepsy. In the form of the attack, he was quite willing to acknowledge that there is no perceptible difference.

Dr. A. D. Rockwell read a paper on

THE VALUE OF ELECTRICITY IN THE TREATMENT OF EPILEPSY.

Having mentioned that he had read a preliminary paper on this subject before the Medical Society of the County of New York in 1878, he said that there is a certain proportion of cases of epilepsy which fails to receive permanent benefit from the use of the bromides, as usually employed, but which apparently completely recover after the assistance of electricity has been invoked, in connection with the bromides. Epilepsy is, in this respect, analogous to chorea. Arsenic is universally acknowledged to be a remedy of the greatest value in this affection; but there are certain cases in which it fails to afford relief, unless its use is supplemented by electricity.

Dr. Meredith Clymer, in some most excellent remarks on the treatment of epilepsy, stated that he had never heard of a permanent cure of the disease under the use of the bromides, either alone or in combination. While this might be regarded as an extreme statement, the suggestion that the best results will follow only when we call to our aid every measure that will tend to increase and develop vital powers generally would commend itself to all. It is not alone, therefore, on the theory of a special influence on the nerve-centres, or even the cerebral circulation, that he employs electricity as an adjuvant to the bromides, but also because of its undoubted and powerful constitutional effects. It is a tonic, but it has both stimulating and sedative effects. In this, as in various other forms of central disease, he almost always associated and alternated central galvanization with general faradization.

Central galvanization is analogous to the effect of the bromides, producing a profound tendency to drowsiness. In some cases sound sleep has been induced with the subject in an upright position, while receiving the current through the brain. He recalled one patient under treatment by central galvanization, who was repeatedly put to sleep within a minute after the beginning of the application. In epilepsy there is a disturbance of the centres of the cerebro-spinal system. There is a hyper-excitability of the nerve-cells, which is dynamic,

rather than physical; and this hyper-excitability is kept in check by galvanism as readily as the bromides.

In one case which he mentioned, the patient, a female, had been under observation for fifteen years. Central galvanization and general faradization had for several years been employed, with intervals of rest, and for four years she had now been entirely free from an epileptic attack, while her mental and moral characteristics, which were formerly very much impaired, had been completely restored. Other satisfactory cases were also related, and in connection with one of them Dr. Rockwell incidentally stated that he had found the effect of the bromides in epilepsy to be enhanced by the addition of one or two grains of chloral hydrate to each dose. The total number of cases in which he had employed electricity was twenty-eight; but ten of the patients had abandoned the treatment too early to allow any conclusions to be drawn from them. In three cases electricity seemed in no way to assist the action of the bromides. In one of these the attacks came on both by day and night, and in the other two occurred only in the daytime. In eight cases the use of electricity was attended with a certain amount of benefit, varying in different instances, but not to such a marked degree as in the remaining seven cases. In two of these the patients recovered entirely, and in the other five there was very decided improvement.

The conclusions arrived at by Dr. Rockwell were somewhat as follows:

First. Electricity possesses a certain value in the treatment of epilepsy. It is not claimed that it alone can cure the disease, but in many instances it is of great service as an adjuvant to the bromides.

Second. In the nocturnal variety its good effects are especially marked.

Third. The methods of application should be central galvanization and general faradization.

Fourth. It is important that the agent should be administered with great care. Anything like a shock to the nervous system should be avoided, and the applications should not be continued too long at a time.

Fifth. The treatment should be continued, with suitable intermissions, for at least two years after the last occurrence of epileptic symptoms.

DR. THOMSON said that he had had no experience with the use of electricity in epilepsy, but he should suppose that its efficacy depended on the peripheral irritation excited by it, as in the case of the red pepper pack to which he had referred.

DR. ROCKWELL said, in reply, that the benefit from this agent is not due to peripheric irritation, for if this were the case we should employ the faradic current and not the galvanic. The effect of the latter, as he had observed in the paper, appeared to be analogous to that of the bromides.

THE NEW BUILDING FOR THE ACADEMY.

Before the Academy adjourned the following resolution was adopted:

Resolved, That the Trustees and Council be, and are hereby empowered to purchase a site or building, or to erect a new building for the Academy, when such a course shall be considered expedient.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, February 8, 1887.

THE PRESIDENT, CHARLES MCBURNEY, M.D., IN THE CHAIR.

FOUR MONTHS' OPERATIVE WORK AT THE NEW YORK HOSPITAL.

(Concluded from page 277)

DR. WEIR stated that on the kidney a series of highly important operations have been resorted to. The first case of the number to which he asked attention is one of

LACERATION OF THE KIDNEY WITH PERINEPHRITIC ABSCESS AND RENAL FISTULÆ.

which occurred in a youth of twenty, who three years before coming under care had fallen a distance of six or eight feet and struck his right side heavily on an iron bar. He had, following this, severe hæmaturia for three weeks, when fever, local pain, swelling, etc., showed that suppuration was progressing in the right lumbar region. An incision was then made by my colleague, Dr. W. T. Bull, and a large amount of pus evacuated. A sinus persisted for a long time, which, healing at times, would break out again and freely discharge matter. Since July last he has been unable to get about by reason of the pain in the flank and also in the rectum. In the left iliac fossa were found much inflammatory hardness and tenderness running upward to a large fistulous opening between the middle of the iliac crest and the ribs. Through this opening a probe could be passed nine inches downward to the iliac fossa. Above the opening near the spine was another through which a probe entered inward four inches toward the kidney. From four to six ounces of pus were daily discharged. The patient was pale, but in fair condition, and anxious to have relief from the persistent suppuration. By the rectum nothing could be felt. The urine was slightly albuminous, but otherwise the examination was a negative one, with the exception of a few pus cells. The amount discharged per diem was between fifty and sixty ounces. No urinary salts were found in the pus discharged from the fistulæ.

A curved incision starting from the upper fistula and running through the lower one and anterior rib, somewhat like the one advised by König, was used to expose the parts, but the tissues were so matted together by old inflammatory action as to yield but little room for manipulation. Instead of finding himself, as the way was finally enlarged by stretching and cutting, in the expected cavity of a suppurating kidney or thickened perinephritic abscess, Dr. Weir came down upon a thin-walled cavity larger than his fist through which could be easily felt the movements of the abdominal viscera beyond. Considerable bleeding occurred from the cavity, and it was temporarily stopped with sponges while the fistulous tract in the groin was opened at its terminus just above Poupart's ligament; a second tract was then found running from the first downward to the pelvis, but too far back to be tapped. A drainage tube was placed in each of these tracts, the sponges removed, and the cavity inspected with the aid of the electric lamp. This discovered that a rent three inches long had been made through the membrane so that the

liver and gall-bladder were plainly exposed; this, probably, would not have been detected had it not been for the lamp. It was sewn up with catgut sutures. Careful examination by Dr. Weir and his colleagues failed to find any remains of the kidney, which was also sought for through the peritoneal opening before it was closed.

The exposed cavity was packed with iodoform gauze and the usual peat bag and other antiseptic dressings over all. Death took place four days later with marked rise of temperature commencing about forty-eight hours after operation, with persistent vomiting and almost total suppression of urine.

At the autopsy there were no signs of peritonitis; the left kidney was in a condition of acute suppurative interstitial nephritis and on its surface underneath the capsule pus was diffusely distributed. At the upper border of the tenth rib on the right side surrounded by dense connective tissue was seen the upper third of the right kidney, its lower two-thirds having been destroyed. This kidney stump formed the upper limit of the abscess cavity which had been opened at the operation. In it were found two sponges which had been left *in situ*, one of which was firmly adherent. It should be stated that on the day of his death, the date of the last dressing, the wound was in an odorless condition. This cavity was bounded internally by the duodenum and spine, anteriorly by the ascending colon and hepatic flexure, and below it communicated by a tortuous sinus with a pus cavity in the true pelvis behind and alongside the bladder and rectum, and extended also through the right sacro-sciatic notch and terminated externally to this in a cavity the size of a hen's egg.

The second case of renal surgery was a huge suppurating kidney, for which

NEPHROTOMY

was done. The man, aged thirty-seven, had had, remarkably enough, symptoms of trouble in his side for only four weeks, and these were of moderate severity, but associated with great weakness, and rather rapid emaciation, and no chills, and no special urinary manifestations. In the right flank was a tumor, painful, the size of a cocoanut, projecting half-way to the ilium, with a deep sense of fluctuation, which the corroborative use of a hypodermatic needle proved to be from retained pus. An incision was made, under the idea that the swelling was more probably a perinephritic abscess, from the distal end of the twelfth rib downward, and, instead of reaching evidences of inflammatory thickening as the cut was deepened, only the translucent peritoneum came into view; through which was seen the tumor moving perceptibly up and down under the action of the diaphragm. Another incision at a right angle to the first, and running toward the spine and up to the quadratus muscle, soon exposed the tumor in another place, when the purplish color proved it to be a largely distended kidney. On opening this with a scalpel over eight ounces of fetid yellow pus were discharged, and the finger in exploring could feel sundry depressions corresponding to cavities in the cortical portion of the kidney. It was not washed out, but two large rubber drainage tubes inserted, and dressed antiseptically. Though the discharge at first was very free, and required frequent changes of dressing, it has of late rapidly diminished, and the patient's condition correspondingly improved, though, at times, a strong urinous odor is perceived in the discharge. Occasionally the cavity is washed out with Thiersch's boro-salicylate solution, as safer than carbolic and sublimate solution.

The case, however, that excited the most interest in the whole of the present operative group from its nature, treatment, and result, has been one of

ABDOMINAL NEPHRECTOMY FOR A HUGE ADENOMA,

a disease which has necessitated removal of the kidney in only one (Czerny) of Gross's collection of 49 cases of nephrectomy for neoplasms. Another has since been published by Albert. Czerny's (*Deutsche med. Wochenschrift*, 1881, No. 32) was in the right kidney of a child, eleven months old. Death took place on the second day from peritonitis. Albert's (Brodeur, *De l'intervention Chirurgicale des les Affectiones du Rein*, 1886, p. 222; also *Wien. med. Presse*, 1885, No. 9) was in a woman, aged forty one, who, two years previously, had had a fall, and subsequently frequent hematuria, etc. Pawlik catheterized the ureters, and differentiated the diagnosis. The tumor, the size of a child's head, was extirpated by a posterior incision. The patient recovered. A third case is also reported by Schönborn (De Jong, *Beiträge zur Nieren extirpation*, Heidelberg, 1885; also *Centralbl. f. Chirurg.*, 1885, S. 24, Beilage). This occurred in a child of three years, and was removed with a successful result.

The present case has the following history. A burly man, a butcher by occupation, was seized suddenly, three years ago, with cutting pain in the left lumbar region, and at that time passed a quantity of bloody urine. This was probably an attack of renal calculus, for other paroxysms came on with not very long intervals, and he frequently noticed gravel to be passed, and indeed, he showed Dr. Weir some fifteen or twenty calculi, principally phosphatic in character, when he was first brought to him by his physician, Dr. Maynard, of this city. In the past year, however, these intermittent attacks have culminated in a persistent pain in the left lumbar region, which is aggravated by sudden motion, by riding, etc. Walking will, moreover, bring on or increase his hematuria. He has lost sixty pounds of flesh in the last two months, and has become blanched from suffering and loss of blood. In the left flank is to be felt a tumor, extending from three inches external to and on a level with the umbilicus, upward and backward under the ribs. This tumor is slightly movable. On bimanual examination the mass seems to be nearly seven inches thick. The amount of urine passed varied from thirty-five to sixty ounces per diem, and on examination showed nothing beyond what might be due to the blood mixed in it.

Under the idea that the kidney enlargement might be due to retained calculi, an exploratory vertical incision, as for nephrotomy, was made in the left loin December 11, 1886, and the kidney, covered only by a thin layer of its fat capsule, exposed by tearing through this. No calculus could be felt, though the posterior surface was pretty thoroughly palpated, and the anterior surface only to a limited degree. A puncture with a needle was made in several places, but did not discover any calculus, nor any cavity. The bleeding was free from the punctures, but easily checked. This examination also showed that the kidney was too much enlarged to

be removed by the usual lumbar incision. It was determined to do nothing further at present, but when the loin wound should have healed that the tumor (for the diagnosis was that of probable sarcoma) should be extirpated by abdominal section. And in the meanwhile, as a corroborative diagnostic means, the quantity of urea daily passed was taken a number of times, as has been suggested by Thiriar, who has noticed that in malignant growths this secretion is materially lessened. It was found in this patient's case to range from 219 to 240 grains per diem.

On the 20th of January, 1887, the patient was again etherized, and by an incision five and a half inches long to the outer side of the left rectus muscle, and starting from the free edge of the ribs, the abdomen was opened, intestines pushed aside with large flat sponges, and the peritoneum covering the tumor incised on the inner side of the descending colon, and the kidney reached. A few minutes' dissection with the finger allowed the root of the kidney to be exposed, when this was easily surrounded with a heavy silk ligature by means of Mott's aneurism needle, and the vessels and ureter tied off *en masse*; a heavy clamp was then applied between the ligature and the kidney, and the latter cut away, and after some tedious tearing of cicatricial adhesions on its posterior surface resulting from the first incision, it was removed. The clamp was then found to have slipped, and allowed a vein which had entered the kidney above the ligature to bleed freely. This showed most happily the control the anterior incision gives in this respect. The bleeding vessel was distinctly seen, and in a moment controlled by a fresh clamp and ligated. Very little blood was lost, though, during the stripping process, which was conducted between the capsule and its fibro-adipose envelope for a short time, quite a smart oozing of venous blood took place. A long pair of dressing forceps was then forced from in front through the old cicatrized track to the loin, and a large sized rubber drain carried in from here to the cavity left by the extracted kidney. The divided and torn edges of the peritoneum, which had covered the kidney, were united by numerous Lembert sutures, thus inverting their edges, and after a final toilette of the peritoneal cavity, which was only so in name, as nothing had entered it, it having been so thoroughly protected by the sponges, the parietal peritoneum was sewn together with catgut, and the abdominal wall closed by silver wire sutures supplemented by additional catgut ones. As some oozing of blood persisted from the drainage tube, several yards of sublimate and iodoform bandage were stuffed into the posterior cavity, and over all peat bags and other antiseptic dressings applied.

The patient's progress was extremely satisfactory; no peritoneal symptoms, and only a persistent gulping for seventy-two hours; no attempt was made to put food into the stomach, and for a week nourishment was administered by the rectum. Temperature, at the highest, in the mouth, was 101.7° F. The urine, for the first twenty-four hours, amounted to but eight ounces, and it was very bloody, due to the operative pressure on the kidney. The second twenty-four hours it rose to twenty ounces, and was of a dark amber color, with only traces of blood in it; urea, 1.01 per cent.; sp. gr. 1.020. On the third day it amounted to forty-nine ounces; and on the fourth to eighty-eight ounces; after which it gradually subsided to about fifty ounces; but the urea still kept lower than normal, but more than before operation. On the sixth day the dressings were changed, and wire sutures removed from the anterior wound, which had healed primarily, and from the posterior opening the gauze bandage stuff was pulled out, everything being sweet and aseptic. On February 8th, the patient was taken out of bed; he now eats heartily, and is on the road to health.

An episode occurred at the termination of the operation that excited some anxiety. On telling the nurse to count her sponges at the close of the operation, she reported that the two flat ones were missing, that there were seven instead of the nine original ones; in a second count, the same result was had, and this original number was corroborated by the superintendent of the training school, who was present. The wound, which was then partially closed, was opened, the hand introduced, and the abdominal cavity hunted over, and Dr. Bull, who was assisting, was requested to verify the search. No sponges were found in the examination, and the closure of the wound was proceeded with. The means for caring for the soiled towels, etc., and for washing sponges, seemed to be so exact, and to be free from possibility of the missing sponges being lost anywhere else than in the patient's belly, that Dr. Weir felt much concern during the first three or four days on this point, being prepared on the first symptom of peritonitis fairly manifesting itself, to open again the abdominal cavity, and resume the search. This feeling was present because, though an examination was found to be negative when made by two surgeons, yet he was conscious of the difficulty of absolutely excluding their presence, as he could not be certain of such regions as the lesser omentum and behind the liver. Events proved, however, that the sponges went elsewhere, although the possibility of organization of an aseptic sponge may be insisted upon by some.

The kidney, when removed, weighed twenty-one ounces, and measured nine by five and a half inches. Its shape was rendered irregular by several projections from its surface, which were marked on its posterior aspect. While the kidney itself was much enlarged, there could be seen after section that its substance had been invaded by an adenoma (as it was pronounced by the pathologist of the hospital) the size of a fist, encroaching upon, but not bursting by ulceration into the pelvis. The mucous membrane of the latter was thickened, and up to the point where severed from the ureter numerous miliary granules were found behind it. Uninvolved kidney tissue was found between the ligature and the tumor.

THE SURGERY OF THE EXTREMITIES

comprises thirty-two operations.

In speaking of the subject of

NECROSIS OF THE LOWER END OF THE FEMUR,

Dr. Weir said that he had made, and seen others also make an error in treating this affection, which he thinks he has now learned to avoid. It is, when much thickening exists at the lower end of the femur not to be content with the piece of exposed dead bone that may be seized and extracted, but to chisel boldly into the thickened end of the bone, even though no opening be found running into it. In very many instances further

trouble may be found existing either in the shape of minute, spiculated, necrosed pieces, or large pieces surrounded by a spongy suppurating involucrum, or even central spongy necrosis, with or without bone abscess running dangerously near the joint line. All these he has found when least expected. He felt warranted, therefore, in urging this point.

In five cases where extensive openings had been made into bones, recourse was had to the suggestion made public by Schede, in 1885, but originated several years earlier by Neuber, and also by Dr. R. T. Morris, of this city, of allowing the cavity to fill up with blood, that this may organize under the antiseptic dressings applied. Either the wound of the soft parts must be sewed up to a small slit, or left entirely open and covered with a layer of gutta-percha tissue, with a hole in it. This is intended to allow the surplus to flow out and also to prevent the dry bandage entirely soaking up the clot. In three out of his five cases (which can be increased to five out of seven, counting two private cases), success was had on the prompt organization of the clot and rapid healing of this wound; that under the old plan of stuffing heals but slowly from the bottom.

ANTISEPTIC IRRIGATION OF THE KNEE-JOINT

with 1 : 20 carbolic solution, was reported for chronic hydrarthrosis of the knee as successfully treated.

Likewise a quite extensive

CHRONIC TENDO SYNOVITIS OF THE PERONEAL TENDONS

was treated by opening above and below and drainage without a very satisfactory outcome; the reason therefor being microscopically shown to be, as König has taught us, owing to tubercular infection of the sheath. It will require opening throughout its whole extent, and thorough dissection, scraping and cleaning with subsequent iodoform packing to effect a cure.

RESECTION OF THE WRIST-JOINT,

after Lister's method, had been done for early tubercular arthritis. In this instance more than usual trouble resulted from the hemorrhage so often induced by the use of Esmarch's rubber bandage. The case promises well, though the long pressure to control the bleeding caused a slight cellulitis of the forearm. Dr. Weir has since in one instance put into use, with gratifying effect, the suggestion made at the Society by Dr. Lange, when using the rubber anæmia, that one should control the rush of blood into the limb after the removal of the constricting band by the pressure of an assistant's finger on the main artery above, so that the full blood supply is only gradually admitted to the limb, and in this way permit contraction of the temporarily paralyzed vessels.

RESECTION OF THE ASTRAGALO-SCAPHOID ARTICULATION

was performed four times in two patients for

AGGRAVATED FLATFOOT.

In three of these operations adherence to Ogston's original plan was followed, of shaving off, after opening the joint, the articular cartilages with a chisel, and then fastening the bones together by ivory pegs driven through the scaphoid bone into the astragalus; in the remaining operation, a little more than the articular cartilage was taken away, and the use of pins was omitted (Stokes's method). The rectified position was maintained easily by a plaster bandage without the support of pegs. The result in the first case, now over four months, is excellent. The last case is too recent to be quoted. Dr. Weir did this for the first time in 1885, in one foot, resorting to, without intending it, Stokes's method—that is to say, removed more than he started out to do, and in the second foot conducted the operation more strictly after Ogston's directions; only he found that his ivory pegs had been soaked all night in sublimate solution, which rendered them so friable that he could not use them, and so he drove in two gilt nails which had been cleaned by scrubbing and immersion in carbolic solution, but were stained by a previous employment in a compound fracture. Whether it was from this or some other cause, the foot went sadly to the bad; the other, without a peg, progressing happily. Severe tarsal inflammation ensued and the young man only got off with a total resection of the scaphoid and astragalus, and parts of the cuboid and os calcis, leaving him, however, in the end a serviceable foot, but prolonging his convalescence for months.

The rather rare operation of

AMPUTATION AT THE HIP-JOINT

was performed by the long anterior and short posterior flap in a man aged forty-six, for huge recurring sarcoma of the soft parts of the left thigh. Beside a large mass reaching nearly to the trochanter in the side and behind, there were several small growths lower down on the face of the thigh. The original removal had been done three years ago by the late Dr. Post, of this city. Recurrence took place within six months of this operation. The main tumor is now some ten inches in diameter. The hemorrhage at the hip amputation was admirably controlled by Lloyd's method, which is to fasten tightly a doubled rubber bandage around the hip so that it rests on the inner side of the tuberosity of the ischium, and its ends are secured above the ilium at about its middle. Pads are placed under the compressing band over the lower end of the external iliac artery and over the sciatic notch. It appears to be the best and least hazardous of the many methods advised to control the blood supply in this high amputation. Next to it in value he places Davy's rectal rod. Not more than two or three ounces of blood were lost in this case. The patient did well without any temperature elevation for forty-eight hours, when signs of gastritis and tympanites came on without diarrhœa, and he died four days after the operation. At the autopsy the stump was found to have progressed satisfactorily. A large aortic aneurism was found and the stomach was studded with patches ranging in size from a silver quarter to a silver dollar, in which the mucous membrane was blackened and destroyed; their edges were sharply defined and of embolic origin, and supposed to have originated from the aneurism. The intestines were distended and much congested in defined areas.

His impression is, that the toxic effect of the bichloride can probably be blamed; at least he conceives that he committed an error which he had in other instances sedulously kept in view. After the stump had been finally closed, to make certain that the two drainage-

tubes were free from coagula, he allowed a 1 : 5000 sublimate solution to flow in through one tube, distend the stump, and to flow out through the other tube, when the dressings, also of sublimate and quite freshly made—*i. e.*, damp—were applied in large quantity. He spoke of this injection of a closed wound as faulty, since he can attribute the production of carbolic acid poisoning to a similar method several years since. The gastric appearances somewhat resembled those shown in a case of death after operation for removal of the uterine appendage, although there frank peritonitis coexisted. In this instance to cleanse the vagina after the use of a tampon, a rather strong sublimate solution was directed by the house surgeon. It is well known that absorption of this drug goes on with special aptitude in the genital passages of the female. Dr. Weir remarked that in spite of the many advantages of corrosive sublimate as an antiseptic, more mishaps had occurred to him in using it than were met with in the days of carbolic acid, and that with iodoform, since he has learned to use it discreetly, no harm has come at all beyond an occasional local irritation.

THE ANTISEPTIC METHOD.

All fresh wounds are irrigated freely with 1 : 5000 or 1 : 10,000 sublimate solution. Catgut, either sublimated or Kocher's, is used. Iodoform when used is either dusted on the line of union of a wound, or on the sublimate gauze or peat bag, which is placed first over the wound. No iodoform gauze (*i. e.*, made by rubbing in iodoform in a sticky gauze of any kind) is employed, except to stuff cavities. Where primary union is sought, it will, if used, often shut up the secretion, and provoke trouble. Where special promptness of union is desired, he much likes to place over the wound a layer of sublimated felted spun glass, a wrinkle of Kümmel's. Over the antiseptic gauze is laid a heavy layer of absorbent cotton, and all secured with sublimated gauze and canton-flannel bandages. Drainage tubes are of rubber; they are kept in a sublimate solution, but they are dipped in iodoform dissolved in ether just before being inserted in a wound. They are removed as early as possible, from the second to the fifth day.

As to the surgeon himself and his assistants; thorough scouring of hands with soft-soap, and subsequent immersion in 1 : 1000 sublimate solution, or 1 : 20 carbolic acid solution, is resorted to. The instruments are scrubbed and boiled, and then put in carbolic solution. Sponges are washed in soft-soap, and kept in strong sublimate solutions, 1 : 2000; all soiled with bad pus or discharges, are at once destroyed.

By mentioning, in closing the list, one case of the very small

OPERATION OF COTTING, FOR AN INGROWING TOE-NAIL,

it is hoped that the artistic diminuendo will be appreciated. Minor operations have purposely been omitted, save in one or two instances where their introduction would justify a remark. The operation of Cotting's often fails, and he has learned from his clinical assistant, Dr. Hartley, how to do it better than he formerly did. He now cuts off much more of the swollen flesh alongside the nail, plunging the knife vertically downward, and sometimes inclining it toward the centre of the toe, so that a generous lump can be taken away, and the incision should run well back beyond the matrix. An iodoform dressing is applied and over the cotton a firm bandage, and with this the patient can keep on walking with the toe exposed in the shoe. In a week usually the dressing is changed.

Lastly, of the 399 patients treated there were 7 deaths, or 1.75 per cent. mortality, and in each of these an operation had been done; in 5 of the 7, death occurred soon after the operation; in two other cases death resulted some time later, as in the patient with tumor of the brain, who lived two and a half months after the operation; and the case of hernia who died three weeks after the operation from pneumonia and Bright's disease. In the 105 cases operated on, there was 6.66 per cent. mortality.

NEW INVENTIONS.

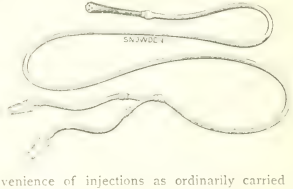
A SIMPLE HOT-WATER VAGINAL DOUCHE.

BY GEORGE ERETY SHOEMAKER, M.D.,

OF PHILADELPHIA

Hot-water vaginal injections now constitute one of the most necessary elements in the treatment of many uterine diseases, yet it is found practically difficult to secure their thorough and systematic application.

If a patient, not under the care of a nurse, be sharply questioned, it will often be found that the general in-



convenience of injections as ordinarily carried out, together with the fatigue to the hand of using a bulb syringe for fifteen or twenty minutes continuously, is such that they are either imperfectly applied, or are often omitted. The accompanying cut represents a simple form of douche, much appreciated by my patients. No fatigue is involved in its use, while the temperature of the water may be regulated at will and constantly increased.

It consists simply of rubber tubing in the form of the letter "Y," armed at one end by an ordinary syringe nozzle, and at the ends of the branches by rubber corks which fit respectively into the hot- and cold-water faucets of the ordinary bath-tub. On properly opening both faucets, water of any desired temperature will run directly through the tubes and will issue from the nozzle. It will occur to anyone that, after changing the nozzle, the instrument may also be used for douching hemorrhoids while the patient is seated over the adjoining closet; vaginal injections should only be administered while the patient lies on the back in the tub, with the hips elevated by a small stool or cushion.

The instrument may be obtained from Mr. Snowden, of this city.

CORRESPONDENCE.

THE PREPARATION OF BLOOD SERUM.

To the Editor of The Medical News,

Sir: Allow me to add a few remarks to those made by Dr. A. C. Abbott, in The Medical News of February 19, concerning the preparation of blood-serum. Several years ago I noticed the advantages to be derived from simply sterilizing the liquid blood-serum and not coagulating it until needed. Using the Salmon culture tube, in which the evaporation is reduced to a minimum, I have been able to keep tubes of liquid serum for many months without any appreciable evaporation and concentration. Even with coagulated serum, the water of condensation remains for months in these tubes, and only the upper narrow portion of the medium shrinks somewhat from loss of water. If I were to use the ordinary test-tubes plugged with cotton I should certainly adopt Dr. Abbott's procedure, as the evaporation is exceedingly rapid even in the d'Arsonval thermostat. When serum is kept liquid for some time and then coagulated in the same tube, it is necessary to shake down or break up the thin pellicle of cholesterin which forms after a few weeks. If the serum is solidified without using this precaution, the entire pellicle will form part of the culture surface. This must be detrimental to any bacterial development.

I have not had any trouble in sterilizing blood serum obtained from blood (beef) collected in slaughter-houses. My only precaution to those collecting it was to wait until a considerable quantity had flowed from the wound.

I have found that turbid serum will clear up very well in the laboratory refrigerator. It is not the very low temperature, but its constancy and uniformity that favor subsidence of the blood-corpuscles. This fact is easily brought home to us when a cylinder of very clear serum taken from the refrigerator becomes turbid in a few moments. The change of temperature causes currents in the liquid and consequent rise of the sediment. The precaution taken by Dr. Abbott of packing in ice seems to me very desirable, as it avoids even a suspicion of bacterial growth, besides furnishing a uniform temperature.

Another precaution which physiology teaches us, but which the beginner may overlook, is to avoid a too low temperature while the clot is forming and contracting. That of a good refrigerator seems to be satisfactory.

Very truly,

Theobald Smith, M.D.

Dept Agriculture,
Washington, D. C., March 3, 1887

NEWS ITEMS.

Wet-nursing at Randall's Island Nursery.—During the past two years the experiment has been tried, in consequence of the large mortality that existed at the Randall's Island Nursery, of placing a number of the children from that institution under the care of nursing mothers, at their homes in and near Mount Vernon, Westchester County. The Commissioners of Charities and Correction now keep from fifty to sixty of them in the country, and the death-rate has been reduced among these infants from thirty per cent. to about five per cent. The cost *per capita* is $13.50 a month, while at Randall's Island it is $7.73. The children are under the personal supervision of Dr. Robert T. Howe, of Mount Vernon; and, once a month, the paymaster from the City Controller's Department pays off the women at his office. Additional provision is also to be made at Randall's Island, where a pavilion adjoining the present buildings is to be erected, at a cost of $25,000. This will accommodate from 1500 to 2000 adults and infants, and will relieve the present overcrowded condition of the Nursery.—*Boston Med. and Surg. Journ.*, March 3, 1887.

Asses' Milk for Infants.—The Administration of the Assistance Publique has decided to employ asses' milk at the Hôpital des Enfants Assistés for infants suffering from hereditary contagious diseases. Owing to the dangers incurred by women in nursing such children, the Administration substituted goats' milk for human milk; but the infants did not thrive upon it. The administration has now provided ten asses, which are kept in the stables of the hospital, with their young. Each ass is capable of nourishing three children besides its own young for the first three months, and two children for the two following months. After this period, it is capable of nourishing one child until the ninth month. Eight children are being nourished in this manner at the present time.—*British Medical Journal*, February 19, 1887.

The Infection of Wet-nurses by Syphilitic Sucklings.—Professor Fournier, of Paris, in a clinical lecture, recently gave the history of a case in which an apparently perfectly healthy wet-nurse became, a fortnight after commencing her duties, the subject of an ulceration on the nipple, subsequently recognized as syphilitic. This, in the meantime, was naturally communicated to the infant. On inquiry, no history of syphilis could be traced, either on the part of the nurse or the parents of the infected infant; but it was ascertained that the nurse had already suckled an infant which had succumbed to symptoms of undoubted syphilis. At the time, therefore, that she accepted the second engagement she was already infected, but the disease was in the period of incubation. Dr. Fournier said he had met with fourteen cases of this description, and advised greater care in the selection of wet-nurses. Two precautions were specially indicated, namely, to engage no woman who had suckled any other than her own child; and if this were not practicable, to require a medical certificate of the last infant's immunity from contagious disease.—*British Med. Journ.*, Feb. 19, 1887.

Venereal Infection Pronounced a Crime.—Some consternation may be caused among a certain class by a recent judgment of Justice Wills of the Central Criminal Court, England. The charge against the prisoner was on two counts, one with having carnal knowledge of an imbecile woman, aged eighteen, and another, under 24 and 25 Vict., c. 100, s. 47, for a "fraudulent assault" upon the same woman, occasioning her actual bodily harm. The harm done was the wilful infection with syphilis. The prisoner was found guilty on both heads, and sentenced to two years' imprisonment for the first, and five years for the second. The most remarkable piece of information is that a man who has immoral

sexual connection with a woman, knowing himself to be suffering at the time from gonorrhœa or syphilis, is liable to prosecution and penal servitude.—*Canada Lancet*, March, 1887.

Preservation of a Human Body After Death.—Indianapolis, Ind., has been considerably excited of late over an instance of remarkable preservation of the human body after death. A lady died in that city some thirty years ago, and her body, incased in an iron coffin, was placed in a vault. A recent examination showed that the body was in a wonderful state of preservation. The *Indiana Pharmacist* says that even the color of her eyes, a deep blue, could be recognized. The hair had grown to a length of two feet. It was supposed by the sexton to have turned to stone, but further investigation showed it to have become changed into that peculiar substance known as adipocere. Adipocere (*adeps*, "fat," and *cera*, "wax") has somewhat the appearance and consistence of cheese, and is a compound of oleic and margaric acids with an alkali. It has usually been formed in bodies that are buried in the earth, and moisture has been supposed to be essential in its formation. In the instance just referred to, the body was in a dry vault. There seems to be no fixed time necessary for this change to take place. One instance is reported of an infant which had been but three months in a cesspool, in which adipocere had formed, while in other cases years seem to have been necessary. —*Science*, January 28, 1887.

An American Journal of Psychology.—A quarterly journal under the above title will shortly be issued under the editorship of G. Stanley Hall, Ph.D., Professor of Psychology and Pedagogics in the Johns Hopkins University.

It will contain original contributions of a scientific character; papers from other journals, including translations, and digests and reviews. While articles of importance in allied fields will be welcome, the main object of the journal will be to record the progress of scientific psychology.

Consumption and Price of Cocaine.—Dr. Squibb, of Brooklyn, has made and sold 76½ pounds of cocaine since October, 1884, using in the process more than 22,000 pounds of coca leaves. The price has fallen from $1.25 to 1½ cents per grain.

Laboratories in Barcelona and Palermo.—The Spanish Government intends to erect a laboratory for research in bacteriology in Barcelona, under the control of Ferran.

A Pasteur Institute will be built and equipped by the Italian Government in Palermo, the director of which will be Professor Celli.

Ambulances for Contagious Diseases in Paris.—There has been, for several years, in Paris, a gratuitous service for conveying to the hospitals those ill with the contagious diseases. To obtain such transportation it is only necessary to inform the police, when a telegram is sent to the ambulance, which responds at day or night. Physicians are required, in ordering an ambulance, to specify the nature of the disease with which the patient is affected. These ambulances are well warmed and equipped, and carefully disinfected after each use.

Professor Mikulicz, of Krakau, has been called to Königsberg to succeed Professor Schönborn.

A New Dentifrice.—The *Gazette Hebdomadaire* contains an article by M. Paul Vigier on the "Use of Steatite as a Tooth Powder." Many years back M. Vigier discovered that the addition of powdered talc to water prevented the deposit of calcareous salts in boilers. Applying this fact to dental therapeutics, M. Vigier has devised a new dentifrice, which, he says, prevents the formation of tartar. The formula is as follows: Powdered steatite, fifteen drachms; desiccated alum or cream of tartar, one and a quarter drachms; powdered cochineal, two and a half drachms; essence of peppermint, twenty drops. Any other perfume may, of course, be substituted.—*Lancet*, February 5, 1887.

Francesco Magni.—This distinguished Italian ophthalmologist died at San Remo on February 2, 1887, aged fifty-nine. He was Director of the Anatomical School at Florence and afterward Professor of Ophthalmology at Bologna. He travelled extensively, and his contributions to the literature of ophthalmology are able and numerous.

He was also an eminent politician, having been Senator of the Kingdom in 1876, and rendered many services to the cause of State medicine.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 1 TO MARCH 7, 1887.

[illegible] Surg. Charles A. [illegible], *Major and Surgeon*.—Ordered for duty as Attending Surgeon. Ordered to this City. *S. O. 41, A. G. O.*, February 18, 1887.

[illegible], *Major and Surgeon*.—Will be relieved from duty at [illegible] Station, to take effect [illegible]. *S. O. 41, A. G. O.*, February 18, 1887.

Gray, Wm. W., *Captain and Assistant Surgeon*.—Leave of [illegible] extended twenty days. *S. O. 43, Department of Texas*, February 21, 1887.

Alden, Wm. L., *Captain and Assistant Surgeon*.—Granted leave of absence for one month on surgeon's certificate of disability. *S. O. [illegible], Department of Texas*, February 24, 1887.

Johnson, P. W., *Captain and Assistant Surgeon*.—Ordered for temporary duty at U. S. Military Academy, West Point, New York.—*S. O. 51, A. G. O.*, March 4, 1887.

Lyon, Geo. L., *First Lieutenant and Assistant Surgeon*.—Granted leave of absence for one month, to take effect about March 1, 1887.—*S. O. 27, Department of Texas*, February 28, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE FIVE WEEKS ENDING MARCH 5, 1887.

Guiteras, John, *Passed Assistant Surgeon*.—Granted leave of absence for twenty one days, February 28, 1887.

Pettus, W. J., *Assistant Surgeon*.—To proceed to Charleston, South Carolina, for temporary duty, February 28, 1887.

ORIGINAL ARTICLES.

NOTES UPON THE USE OF CORROSIVE SUBLIMATE IN OBSTETRICS.

BY EDWARD P. DAVIS, M.D.,

OF PHILADELPHIA.

In the six years which have elapsed since Koch brought prominently to the notice of the profession the bichloride of mercury as an antiseptic,[1] it has been widely used in obstetrical and surgical practice, superseding, in many cases, carbolic acid and other less powerful agents.

The researches of Koch showed that in solutions of 1 to 1000 corrosive sublimate killed, by one immersion, the spores of anthrax bacillus, one of the most resistent of the pathogenetic microörganisms. It was also shown that in solutions of 1 to 50,000 the same effect was produced by a longer immersion. In 1 to 5000 a single immersion was generally, but not invariably, sufficient to kill all spores of bacilli; and the limit of efficiency by renewed and prolonged use was between 1 in 20,000 and 1 in 50,000. Forster[2] showed that micrococci were destroyed, when upon the hands, by a solution of 1 to 1000, and also by a solution of 1 to 5000; these experiments were made by dipping the fingers in peptonized meat solutions and Koch's culture gelatine.

The practical advantages of sublimate may be summed up as follows: in solutions of equal antiseptic strength sublimate is less irritating than carbolic acid (Fürst, *Die Antisepsis*).

The urethra, urinary bladder, and peritoneum are, however, much more susceptible to irritation than the uninjured mucous membrane of the genitalia. The use of the sublimate has resulted badly in a case cited by Krukenberg and Ribbert (*Centralb. für Gyn.*, 1885, No. 2), when it produced a violent inflammation when brought in contact with the peritoneum. The solution used was 1 to 5000. Sublimate is free from color and odor, which is at once an advantage and a danger. It is a good deodorizer, and it also checks secretion. It is less volatile than carbolic acid; this is, however, offset by its readiness to combine with other substances. A small bulk of sublimate is needed, and it is cheap.

Experience has shown the disadvantages attending its use to be as follows: most important of all, its poisonous properties; this point will find amplification further on. Its disinfectant power is greatly lessened by the presence of free albumen. Koch has noticed this; Mikulicz[3] has for this reason raised the question whether sublimate should not be reserved for cleansing the hands and the unbroken skin. Fluid which contains septic matter can be removed by preliminary irrigation, and a disinfectant may follow, but the successful disinfecting of necrosing tissue in the uterus is not always efficiently done by sublimate, for the reason just stated. Lister has found that sublimate forms an insoluble albuminate of mercury which is irritating, and this fact has led him to combine sublimate with ammonium chloride (*Pharmaceutical Record*, May 15, 1886).

Repeated irrigations with sublimate solution result in the accumulation of a compound whose mercurial concentration increases (Fürst, loc. cit.) by the formation of the albuminate and other compounds. A minor inconvenience, which can probably be readily avoided, is that reported by Jeannel in the maternity of Saint Eloi (N. Y. *Medical Record*, July 3, 1886). He found that cocaine was decomposed by sublimate solutions.

Sublimate damages instruments. In comparison with carbolic acid, it much more readily decomposes; it is peculiarly liable to enter into combination with a number of foreign substances. Rubber, sugar, extracts of various kinds, fats, and other substances promote its decomposition. This is especially true of sodium chloride, a moderate amount of which greatly increases the absorption of the mercurial. The constant presence of sodium chloride in the animal body suggests at once its influence upon the absorption of corrosive sublimate.

In spite of these disadvantages no agent has apparently produced such strikingly brilliant results, as shown by statistics, as has sublimate. This is seen in the early reports of clinics. Winter, Leopold, Szabó, Bidder, Olshausen, Iverardi, Keller, Schauta, Tarnier, and Garrigues reported a great diminution in septic cases of all kinds; in some of these clinics the solution of 1 to 5000 was used for vaginal douches, and stronger solutions to cleanse the hands and external genitalia; in others the douches were of the stronger solutions also.

It is not to be expected that the widespread use of so powerful an agent could be devoid of danger, and the number of cases of accidents reported is quite sufficient to cause us to criticise the methods of using sublimate, and endeavor to assign it to its proper place in obstetrical practice.

Bull's collection of fatal cases[1] and Butte's notes of twenty fatal cases[2] have been sufficient to arouse attention, while instructive isolated cases, like that reported by Fleischmann,[3] have even led to a feeling

that this agent should be banished from among the antiseptics used in midwifery.

While we cannot at all agree with Thorn, that vaginal or intrauterine douches of sublimate solutions should never be given, it is interesting to note the results which can be obtained when sublimate was not used. The statistics of Ehrendorfer, of the Second Clinic in Vienna, are interesting in this particular. The material from which these statistics were taken was used extensively for clinical teaching by bedside instruction in "touch courses."

Seven hundred students availed themselves of these advantages in three years.

The lying-in ward occupied the former site of an old pest-house, and beneath it ran the sewer of neighboring infantry barracks; it formed a part of a large general hospital. The nurses in attendance were, many of them, of very ordinary intelligence, and incapable of carrying out a system of treatment at all complex. The patients furnished examples of the results of ignorant practice among outside midwives, and also exhibited the deformities common among a poorly nourished population.

Pathological labors were not infrequent, and hence operations were often performed. Summarizing briefly the results of the years 1882, 1883, and 1884, Ehrendorfer reports 2898 births, with mortality of 0.51 per cent.; 2669 births, with mortality of 0.33 per cent.; 2778 births, with mortality of 0.32 per cent. Two Porro operations and one Cæsarean section entered into the statistics of 1884. Vaginal and intrauterine douches were never given without a positive indication. The antiseptics used were carbolic acid and iodoform; no pad or occlusion bandages were employed.[1]

This treatment is, essentially, thorough external cleanliness, non-interference with the normal puerperal state, and antisepsis with the agents mentioned. It is interesting to know that a year ago sublimate, 1 to 1000, was introduced in this clinic for cleansing the hands of those manipulating the patients; and while the custom of non-interference still prevails, the statistics have become better, a result attributed to the mercurial. These results do not represent ideal antisepsis, but are to be studied as showing the value of certain features in this mode of treatment; they lack the benefit derived from a proper use of sublimate.

As aiding in arriving at a correct understanding of the proper use of the mercurial, let us consider some of its untoward effects.

It has been supposed that only in the case of abraded surfaces could intoxication with solutions of 1 to 1000 and 1 to 2000 occur. Fleischmann, however (loc. cit.), reports a fatal case from vaginal injections before labor, when the vagina was probably intact. While it is true that an amount of the solution may have entered the uterus and have been retained there sufficient to have caused intoxication, yet all ordinary means, successful in many other cases, were employed to guard against this accident, and such entrance of sublimate solutions to the partly dilated os uteri has doubtless frequently occurred without intoxication. A fact of importance in this case is that the patient was suffering from diarrhœa previously acquired, and this would indicate a susceptibility on the part of pregnant women suffering from intestinal disorders to mercurial poisoning.

Fleischmann's case is especially of interest as a case of intoxication in a pregnant, but non-parturient woman. Recent experiments by Doléris and Butte[1] were made upon animals by giving vaginal injections of sublimate to non-pregnant bitches, and also by wounding the mucous membrane and skin, and injecting these wounds. The solution used was that of Van Swieten, 1 to 1000 of corrosive sublimate. The experiments upon wounds were not limited to dogs, but included rats and rabbits also. The first experiments were two in number, and consisted of allowing one quart, and sometimes more, of the solution to irrigate the vagina of a healthy animal, in one case for eight consecutive days, several times daily. Diarrhœa was in each case produced, with a slight rise of temperature, both of which symptoms ceased without the cessation of the injections. The surface of the mucous membrane became dry, pallid, and its elasticity was much diminished.

The next experiments were upon wounds produced for the purpose in the subcutaneous tissues of the back, in the abdomen, the thigh and the groin. It was noticed that when the wounds were of such a nature that the solution did not accumulate, but merely irrigated the parts, the ill effects produced were limited to diarrhœa of moderate severity. When, however, the irrigation was prolonged, or the wounds formed pockets or recesses, allowing the accumulation of any quantity of the fluid used, fatal results followed in a period of time ranging from ten to twelve days. The experiments were ten in all, and from them the performers drew the following conclusions, which they divide into experimental and practical.

Sublimate irrigations, 1 to 1000, upon healthy, intact mucous membranes, are not apparently dangerous, and excepting the minor inconveniences which followed the first injections, they are inoffensive. Sublimate irrigations, 1 to 1000, when employed upon large wounds, produced sanguinolent diarrhœa, with tenesmus, violent colic, vomiting, albuminuria, progressive enfeeblement and death, preceded by a reduction of temperature.

The anatomical lesions found by post-mortem examination were hyperæmia, submucous hemorrhages and necrosis of the mucous membrane of the large intestine.

The kidneys were in a condition of acute parenchymatous nephritis, the straight tubules filled with calcareous deposits.

These observations correspond to those of Prevost, Charrin and Roger.

The excess of urea in the blood indicates uræmia as the cause of death.

The practical conclusions which the experimenters adduced were the following:

Sublimate injections must be used with great

[1] Archiv f. Gyn., xxvi. 2.

[1] Archives d'Obstétrique, Dec. 25, 1886.

caution; in cases where wounds and lacerations of the vagina and uterine neck exist they should not be employed.

The elevation of temperature observed in the case of women was not present in animals, because the latter were not also laboring under a process of septic infection from necrosis of bruised and lacerated tissues; intestinal necrosis is also much more severe in the case of the human subject.

Elevation of temperature is not a symptom of intoxication, but, on the contrary, lowering of the temperature is a well-established symptom.

Daily examination of the urine should be practised when sublimate is used; albuminuria is an early symptom of intoxication, as is the yellow discoloration of Fehling's solution when heated with the suspected urine.

Analysis of the blood affords the most reliable means of knowing the extent of the uræmic poisoning.

These writers end by saying that while sublimate is excellent for the hands and for articles used about the patient, it should not be used upon the patient's body when any solution of continuity exists.

In surgery its employment should be restricted to superficial wounds of small extent, upon whose surface irrigation is rapidly performed.

All efforts to diminish the toxic effects of sublimate by dilution of the solutions employed or the use of other salts of mercury should be abandoned for the use of innocuous antiseptics.

While we cannot agree with the last statement made by Doléris and Butte, their cautions have weight, and their experiments are of interest. A case which illustrates in the human subject the ill effects which their method of injections produced upon wounds is reported by Dr. W. T. Belfield, of Chicago, in the N. Y. *Medical Record* of August 21, 1886. A patient was operated upon for calculus and enlarged prostate by suprapubic cystotomy. The wound was irrigated once daily with 1 to 1000 sublimate solution, the bladder with boracic acid solution. On the eleventh day after operation the patient had diarrhœa, with falling temperature, metallic taste in the mouth and prostration; death ensued on the thirty-sixth day, with marked symptoms of intoxication; post-mortem examination of the bladder only was allowed, which was free from suppuration.

One of the more remote effects of mercurial intoxication is found in lesions of the peripheral nerves, described by Letulle, at the Paris Académie des Sciences.[1]

Gustave Braun has reported[2] 9 deaths in 475 cases, from the use of vaginal injection of 1½ litres (about 1½ quarts) of 1 to 1000 solution. He also observed intoxication following the use of 1 to 3000; mercury was found in the feces, and death occurred in sixteen days. He found mercury in the feces of patients receiving injections of 1 to 4000; he cautions against its use in cases where solutions of continuity exist, and the patient is anæmic.

[1] L'Union Médicale, January 15, 1887.
[2] Wiener med. Wochenschrift, No. 21.

Fürst (loc. cit.) mentions four fatal cases of sublimate poisoning, and sixteen in which recovery ensued. A portion of these cases are doubtless included in the reports of fatal cases to which allusion has been made. He derives the following observations from these cases:

Unnecessarily great quantities of stronger solutions should be carefully avoided.

Repeated injections and continuous irrigation are exceedingly dangerous. Residual fluid should be carefully expelled; care should be taken to prevent uterine atony and dilatation. Anæmia greatly predisposes to poisoning.

Albuminuria is a positive contraindication; this is true in the use of carbolic acid also. The rénal condition which normal pregnancy occasions causes a peculiar susceptibility to poisoning from mercury; the comparative immunity of surgical patients is mentioned as pertinent. Primiparæ are more exposed to intoxication from their greater liability to eclampsia and its attendant renal conditions. Patients suffering from pyrexia are more susceptible.

The danger of the injected fluid passing through the Fallopian tubes should be borne in mind. An interesting case reported by Vohts (*Hospitals Tidende*, 1884, No. 22), illustrates this danger.

While the cases cited can lay no claim to numerically including the reported accidents in the use of sublimate, its dangers are apparent. The question arises, How can so useful and powerful an agent be used safely? The full answer of this question will indicate a rational antisepsis in obstetrics.

The statistics of Ehrendorfer prove that non-interference with normal conditions results well, and that innocuous antisepsis, with cleanliness, produces excellent results.

The success obtained by Garrigues in the prophylactic treatment by sublimate and occlusion (*Antiseptic Midwifery*), and the excellent progress made under the same treatment at the Boston Lying-in Hospital (Richardson, *Boston Med. and Surgical Journal*, for January 27, 1887), with the results of similar treatment in various degrees of exactness in other maternities, leave no doubt of the value of such a routine. First in importance is non-interference, rationally conducted and supplemented by the rigid disinfection of all persons and things which come in contact with the patient; this is best accomplished by the preliminary use of potassium soap (Kümmel, of Hamburg, *Archiv für klin. Chirurg.*, 1886, xxxiii. 3, p. 531), in cleansing hands and instruments, and the patient's external parts; then the faithful use of sublimate solutions, 1 to 1000, or 1 to 2000, for the unbroken skin, and when the mucous membranes are *undoubtedly intact*, the use of the weaker solutions, *per vaginam*, may safely be allowed before labor; these injections would be indicated only in a healthy patient after all means had been used to ascertain the condition of the bowels and kidneys. For the disinfection of instruments and metallic articles potassium soap and five per cent. solution of carbolic acid are sufficient (Kümmel, loc. cit.). The disinfection of apartments, as suggested by König, by vapor of sublimate solution has been

tried at Göttingen, by Kreibohm, and at Berlin by Heræus (*Centralblatt für medicin. Wissensch.* for January 15, 1887), but without success; cultures used in these experiments were not sterilized. The occlusion bandage of Garrigues (loc. cit.) is largely efficient against the germs of the atmosphere. This bandage includes the compression bandage in the treatment of the breasts, and coupled with the careful disinfection of the nipples, prevents the increased susceptibility which the pyrexia, known so long as "milk fever," has always produced. The practical application of these principles to private practice has been illustrated in the article of Fry, in the *American Journal of Obstetrics*, for April 1886, and by Garrigues.

In pathological cases the vaginal and intrauterine douche will be considered appropriate.

We have seen that the repeated use of sublimate upon wounded surfaces is dangerous, and that it forms irritating compounds with the albumen of necrosing tissues. The combination of sublimate with ammonium chloride, as done by Lister, is indicated, and in this connection the experiments of Lepine, as quoted in the *Fortschritte der Medecin.* of January 1, 1887, are of interest.

His results, while not proven, indicate the possibility of so mixing the most efficient soluble antiseptics known that combination of the ingredients of the mixture shall result, and a great diminution of irritant effects with increased disinfecting efficiency. If, however, one or two intrauterine applications of sublimate prove without ill effect, the danger of repeated use should not be ignored. Solutions of sublimate for douches should not be stronger, when used where lesions of continuity may exist, than 1 to 4000. Failure to disinfect the uterine cavity by such solutions, as shown by continued pyrexia, should urge seriously upon the physician the propriety of using the dull curette, and the after-douche of thymol, carbolic or boracic acid, as practised by Carl Braun and others.

The clinical studies of Johnson, in Stockholm (*Medicinisch-Chirurgische Rundschau* of December 15, 1886), show boric acid and its compounds to be innocuous when moderately used, and to be particularly adapted to patients suffering from albuminuria, as the quantity of albumen was lessened and diuresis induced. In a series of articles upon the different antiseptics by Bergonzini and Frignani the writers state that boric acid differs from corrosive sublimate and carbolic acid in that it does not form obnoxious compounds with the tissues; and it is commended as an efficient and innocuous agent.[1]

The objections raised by Mikulicz to iodoform as an antiseptic, have found reinforcement in the work of Heyn and Roosing[2] in Copenhagen, who have concluded that iodoform is not only not an antiseptic of value, but that it may itself contain poisonous germs. It is thought by some that the insufflation upon vaginal wounds of iodoform closes their surfaces against absorption, and it has been commonly used for this purpose. The employment of such a local occlusion dressing for vaginal ulcers deserves study and experiment.

The proposal to banish corrosive sublimate from obstetrical practice, and its excessive use are equally irrational; the line of progress lies in a careful study of the manner of employing so valuable an antiseptic. If these notes prove of service in such study, they will fulfil their object.

LIGATION OF THE EXTERNAL CAROTID ARTERY.[1]

A SYNOPSIS OF FIVE SUCCESSFUL CASES.

BY LEON A. WYLIE, M.D.,

Prior to 1878 there were recorded only 67 cases in which the external carotid artery alone was tied; 3 of these died, and these fatal cases were from gunshot wounds in military practice. 1 died on the table from the effect of hemorrhage before the ligature could be applied. In the other 2 the cause of death is not given. Of the 67 cases, hemorrhage after deligation occurred in 5, none of which proved fatal. In 4 of these cases the bleeding was noted as at the seat of lesion beyond the ligature, and in 1 the point where the hemorrhage occurred is not stated. The artery was tied on both sides in 6 patients, and all recovered.

Since the demonstration by myself in 1878 of the comparative regularity of origin of the branches of this vessel, together with the great mortality following deligation of the common carotid, as shown by an analysis of 794 cases, the application of the ligature to the common trunk for a lesion in the distribution of the external carotid beyond the origin of the lingual branch has been abandoned, and deligation of the external trunk has become the accepted operation. The introduction of the catgut ligature has added an element of safety to this procedure which has, in my opinion, almost entirely removed the danger of secondary hemorrhage.

Without further discussion of its merits, I wish to add to the record the following cases:

Case I.—Moses Millspaugh, carpenter, fifty-six years old, married, United States, came under my care through the courtesy of Dr. Bayley, of this State, on January 6, 1885. The patient's history contained nothing of interest with the exception that he had been a constant chewer of tobacco until one year ago, when he stopped on account of a painful sore which appeared on the left buccal wall, at the point where he was in the habit of holding the tobacco while it was being saturated with saliva. The ulcer and induration gradually spread, and when I first saw him there was an evident epithelioma involving the buccal wall and a limited portion of the alveolus of the lower jaw. The lymphatic glands of the left upper carotid and submaxillary triangles were enlarged and indurated.

On January 9, under ether narcosis, I dissected out the glands, and finally, in order to prevent

bleeding, but chiefly to retard the recurrence and further development of the neoplasm, placed a catgut ligature around the left external carotid artery below the lingual and about one-third of an inch above the bifurcation. As is my rule of practice, I also tied the superior thyroid artery about a quarter of an inch beyond its origin. Antiseptic dressing,

bone drain, and silk sutures. I then excised the epithelioma, cutting well away from the margins of the disease. The patient recovered without hemorrhage or any unfavorable symptoms, and, on January 31st, twenty-one days after the operation, he left the city for his home.

Case II.—P. H. W., thirty-seven years, journalist, married, United States, came to me through the kindness of the late Professor Frank H. Hamilton, on June 26, 1886. The patient had for years been a confirmed smoker of cigars and cigarettes, and fifteen months before I saw him a painful ulcer appeared on the under surface of the left side of the tongue near the tip, just where the end of the cigar rested while holding it between his teeth and lips.

When examined, the anterior portion of the tongue was indurated and swollen in part, and in part occupied by the characteristic ulcer of epithelioma. The posterior limit of the induration crossed the tongue obliquely, being about one inch from the tip on the right side, and two inches along the left border. The glands of the left side of the neck were infiltrated. On June 29th, under ether, I dissected out the glands of the neck (left side), and tied the external carotid a quarter of an inch above the bifurcation of the primitive trunk. The superior thyroid was also tied. Catgut ligatures were employed. Bone drains and catgut sutures. I then extirpated the tongue and floor of the mouth. The organ was divided one inch behind the line of induration. The patient recovered without a bad symptom, and is now, eight months after the operation, free from all evidence of epithelioma, and in active business.

Cases III. and IV.—Zoe Magi, forty-seven years, housewife, Italy, came under my observation on June 14, 1886, having been sent to my clinic at the Polyclinic by the kindness of Dr. Abruzzo, of this city. Sixteen months before this date, following the cessation of her menstrual flow, she noticed that the parotid gland of each side was enlarged. The swelling of these organs continued, the mouth became dry from lack of saliva, and deglutition was difficult. Up to the time of the appearance of the tumors of the parotid the health of the patient had been good.

On admission to Mt. Sinai Hospital the tumors were about of equal size, extending from the upper level of the ear to the level of the chin. A diagnosis of bilateral sarcoma was made. The patient was told that an operation would very probably not effect a cure, and that facial paralysis would result. She insisted upon an attempt to give her even temporary relief. On June 14th I tied the right external carotid between the lingual and the bifurcation of the primitive trunk, preliminary to the removal of the neoplasm. The superior thyroid was then tied. The hemorrhage during the dissection was insignificant.

The wound healed quickly, and on September 21st the second operation was performed. On account of the extension of the tumor down the neck, I had great difficulty in getting at the external carotid, which was entirely overlapped by the new growth, and was pressed deeply in the neck. The bleeding was so troublesome that I threw a temporary loop of catgut around the common trunk one inch below the bifurcation, which controlled the hemorrhage until I passed the ligature around the external trunk just at its origin. After removing the neoplasm, I found the ligature had been applied on a level with the crotch of bifurcation. This was nearer the primitive trunk than I had intended, but when it was applied I could not see the exact location of the ligature on account of the tumor. It was left in this position, and the superior thyroid was also secured. No bleeding occurred, and the patient recovered and left the hospital on November 9th. This is probably the only case on record in which the ligature was applied so low down, and well demonstrates the safety and efficiency of the catgut. The microscopical examination of the neoplasma proved these to be round-cell sarcoma.

Case V.—In this case the common and external carotid arteries and the superior thyroid branch were tied for aneurism of the internal carotid. The internal trunk was affected with atheroma to such an

extent that the ligature could not be applied to this vessel. The operation was performed on July 24, 1883. The tumor rapidly diminished in size, the patient leaving the hospital on the twenty-third day after the operation. She is now living and well.

THE EARLY RECOGNITION OF INCIPIENT MELANCHOLIA.

The general practitioner has no hesitancy in saying that a case of impaired physical health, with loss of sleep and confirmed mental depression, in conjunction with ideas of suspicion, hallucinations, illusions and delusions with suicidal or homicidal tendencies, is one of melancholia, and generally advises the friends to place the patient in a well-conducted asylum for the insane.

With symptoms less pronounced there is often considerable doubt as to the state of the patient's mental condition, and the advisability of hospital care. The making of a positive diagnosis is delayed, and not infrequently much valuable time is lost in the proper treatment by failing to consider the importance of the early symptoms of the disease. In some cases to say where sanity ends and insanity begins is indeed at first sight a difficult task; but a careful examination of the clinical history will generally be rewarded by a correct conclusion. It is extremely difficult to draw a theoretical line between mental health and disease, but practically there are no greater obstacles than exist in distinguishing between bodily health and disease. The great characteristic of all insane conditions is the excess or deficiency of normal mental activity in conjunction with impairment of will-power. The disturbance may be general, leading to mental confusion and incoherency of thought; or it may be so limited that the deranged ideas will be circumscribed by particular lines.

In the examination of a case of suspected lunacy, the motives which govern the conduct and the reason therefor should be ascertained, if possible, that judgment may be made as to how far unsound influence has prevailed. In cases in which the insanity is not readily apparent, it is of the utmost importance to have a clear conception of the natural or normal mental capacity of the individual, and also to consider how far the mind has been formed by social position, educational training, and religious teaching. The departure from the individual standard and from that usual to the majority of mankind in similar circumstances will very accurately gauge the amount of mental disturbance. No single word so perfectly describes this condition as "alien."

There is a class of persons whose physical and mental powers are so harmonious in development and operation that there is no undue depression or exhilaration produced by the incidents of daily life. Whether they meet with adversity or prosperity the serenity of mind continues. As a rule, when these minds become deranged they break down suddenly. The progressive steps or stages which characterize the majority of cases of melancholia follow each other with surprising rapidity. The period of confirmed depression, with impaired bodily health, to which I desire to call attention is absent, or of such short duration that it is unobserved. The onset is short, the features of the disease prominent, and the insanity unmistakable.

The mild forms of melancholia seldom begin suddenly. The mental symptoms are almost always preceded by impairment of physical health. The appetite is poor or capricious. If there is a relish for food, digestion is imperfectly performed, and there is consequently loss of bodily weight. The functions of the liver are disturbed, and constipation is one of the most constant of all symptoms. Vertigo is frequently present. Some cases complain of headache, while others may have a feeling of "weight" or "pressure," or there may be "a lightness of the head." The pupils are frequently dilated, the hands cold and damp, and the purplish tinge which extends about one-third of the way up the forearm in many severe cases begins to appear. An anæmic condition of the blood and consequent limitation of the proper nourishment of the brain impairs the normal supply of nerve force and the integrity of the mental faculties. A feeling of lassitude takes the place of the natural buoyancy of the individual, and the patient becomes conscious that there is something wrong with him. Corresponding to the failure of physical strength, there is a flagging of the mental powers, and an aversion to intellectual pursuits. The patient is apt to become absent-minded, and loses interest in what is going on around him. There is difficulty in fixing the attention on any subject for more than a short time. Sleep is broken by depressing dreams or periods of wakefulness. When a good night's rest is obtained, the patient is not sufficiently refreshed in the morning to bear the accustomed burdens of the day without languor. Exertion is no longer a pleasure, and indifference to activity is manifest. There is a change in the facial expression, an unnatural manner of doing the common things of life, peculiarities or neglect in adjusting the dress, and the general appearance of the patient becomes indicative of the mental commotion going on. No calamity is so great, no misfortune so irretrievable, no affliction so heavy as the distress of a diseased imagination. Transient misgivings, moody apprehensions, a consideration of undefined terrors, frequent self-examination of imaginary short-comings, increased emotional susceptibility, slowly but surely change the countenance, and, if left unchecked, the ravage may go on until the change is apparent to the most casual observer.

Change of character and disposition is a pretty constant concomitant of the incubation of mild cases, and a marked premonitory symptom of the more aggravated forms. From being mild, pleasant, and cheerful, there is a gradual change to peevishness, irritability, and fault-finding. Hours of unhappiness result from trifling circumstances. Trivial incidents are magnified to mean a slight, or to have some special reference where nothing of the kind is intended. In certain frames of mind an unconscious

smile, or thoughtless gesture, may be interpreted as a derision or a special pointing out. Ordinary conversation may seem to have a hidden meaning, and a personal application is frequently made of a general public discourse. Morbid selfishness becomes a prominent trait. Suspicion, apprehension, and evil forebodings, with constant tendency of mind to turn inward and dwell upon self, leave no opportunity to cultivate friendship, to relieve distress, or for the higher and more noble purposes of life. Constantly viewing imaginary wickedness prevents pointing to the way of holiness. No consolation can be offered when the mind is overwhelmed with alleged misery. Eyes that generally have no tears for their own suffering are unable to weep for others. No generous impulses fill the heart when worldly possessions seem about to vanish. There is no food for the poor when starvation or the almshouse appears in the near future. Instead of attempting to supply the requirements of those naturally depending upon them, there is an inability to follow the usual vocation of life, or there may be a closer application to business than the circumstances require.

A complete revolution in the religious and moral ideas without adequate cause is open to suspicion of mental aberration. When one who has always lived an upright, consistent life begins to make self-accusations of evil-doing, and unusual personal application of those passages of Holy Scripture which bear upon the future punishment of the wicked, he is fast travelling the broad road which rapidly leads to the supposition that the unpardonable sin has been committed, the day of salvation passed, and only future punishment awaits him. The temporary anguish excited by a sense of guilt under the workings of the Holy Spirit in the wicked and depraved is soothed by hope of forgiveness, but the continued remorse of a diseased condition grows deeper and keener, till self control is lost in a paroxysm of frenzy, or recovery takes place. The operation of the Holy Ghost upon the mind soon leads it out of darkness into marvellous light and useful activity, but the despondent ideas of mental derangement unfit the individual for the duties of life in proportion to the amount of disease. Perhaps the life of John Bunyan furnishes as good an example as can be given. The distressing ideas which harassed his mind under conviction passed away as hope entered, and his unequalled *Allegories* are a permanent monument to his intellectual clearness. Unstable religious ideas, leaving the accustomed denomination and place of public worship for another, only to change again in a short time, have been the early evidence of approaching melancholia in certain cases. The religious thoughts and actions of a disordered imagination are as unlike the fruits of true religion as the latter are unlike fanatical and hysterical excitement. Morbid religious feelings are unusual and irrational, and are accompanied by unsound notions and actions in regard to other subjects. A melancholic whose ideas tend to religious subjects can give no true or just reason for his depression, but "a broken and contrite heart can prove its sin." The remorse of the insane produces no healthy, abiding reform in the life and character of an individual, but in the sane it does.

A painful change of feeling, without undisputable reason, toward former objects of respect and affection should excite the gravest fear of mental unsoundness. It is one of the strongest indications of the insane state when ungrounded suspicion begins to poison the mind against those who have been formerly loved and trusted, and who can have no possible motives except the welfare of the individual. When the actions of dutiful children, doting parents, or the long-tried companion of life, appear to be working against one for evil, reason may well be said to tremble on its throne. As distressing as are these thoughts, they are fraught with no less disastrous consequences than the other extreme when love seems to be intensified in the face of alleged adverse circumstances which may lead to the destruction of more than one life, to avert some unreal calamity. Although what is known in Maine as the Edgecomb tragedy occurred almost forty years ago, it illustrates the truth of this remark as perfectly as if it had occurred to-day.

A man in comfortable circumstances, by the name of Pinkham, thought his farm and money could give him no more happiness, and regarded the pleasures of this world as a bubble; that he had nothing more to live for, and became tired of seeing the sinfulness of his fellow-creatures in this wicked world. He said, like the Psalmist, he knew his enemies would swallow him up, for they were many, and fought against him. He had also hallucinations of sight. He calmly wrote a detailed account of his feelings and ideas, and what he proposed to do, and placed it in the family Bible, and then, with an axe, deliberately murdered his wife and four children, in order to see them safely free from the bonds of this wicked world. He immediately after took his own life with a razor.

Not infrequently there is a most decided change in the sexual desires in connection with despondency. There may be either great exaggeration or partial or total abolition ;, sometimes there is a perversion of sexual instinct. Lascivious conversation and obscene conduct in the habitually modest and chaste are almost invariably conjoined with disease of the brain. The sudden prominence of the sexual propensities over the will and caution often lead to the most revolting and unreasonable actions and crime.

The organs of special sense may participate and play a very important part in the lowness of spirits before positive delusions or hallucinations become established. There are cases on record where the loss of sight or hearing have seemed to be the exciting cause of the mental ailment. The hearing may become remarkably acute, and ordinary sounds produce unpleasant impressions. Conversation in an undertone or at a distance may be distinctly heard, which could not be understood in the normal condition. The striking of a clock has been mistaken for the tolling of a funeral bell. In pronounced melancholia hallucinations of hearing are a very common symptom. It is not uncommon to hear the deranged remark, "Things don't look

as they used to; everything has changed." I recall the case of a farmer who said the grass had turned blue, his potatoes were all small, and the sun appeared as seen through smoked glass during an eclipse. There may be complaint of unpleasant odors and poisonous gases where none exist, or delight may be experienced by an unpleasant smell. The taste may be obliterated or perverted. The power to detect the flavor of food is so impaired in some cases that there is a frequent complaint of improper cooking, or a suspicion that deleterious substances have been introduced. Patients frequently imagine they taste poison in their food. In perversion of the taste, the most loathsome as well as indigestible substances are devoured with avidity. In some cases the mind is so fully occupied with depressing ideas that common sensibility is apparently lost. The hair or whiskers may be pulled out, or the fingers pricked or bitten till they bleed, without pain being felt. In some, strange and unnatural sensations are experienced, as when electric shocks or creeping sensations are alleged to be felt. Sometimes abnormal sensations are referable to the alimentary tract, as when the throat is supposed to be closed, or the walls of the stomach grown together or filled with indigestible food. In many cases the bowels are thought to be incapable of action.

A striking peculiarity of some cases is the loss of interest in self and family as well as in the affairs of the world. An apathetic state is reached when no concern is manifested for the welfare of self or family, although there may be no thoughts of self-destruction, yet life has no attractions. Healthy human affection is lost, and everything is regarded with listless indifference. Exceptionally, some sudden shock may arouse them to a sense of duty, and while administering to the necessity of some one near and dear to them, their own restoration may take place; but this is not common.

Reticence, or almost complete silence, is a marked feature as melancholia becomes more confirmed. If the patient enters into conversation he talks upon subjects connected with his depressed ideas, and is unable to turn from one subject to another, as in health. In most cases there is a tendency to avoid the society of former companions and friends, and to become seclusive in habits in conjunction with this state. If a neighbor makes a friendly call the patient may quietly withdraw without making any excuse for his conduct. The desire to be alone may become so great that considerable difficulty will be experienced in preventing them from leaving the family circle, to seek entire solitude. The poet has very accurately described in the following lines the condition of the severe types of the disorder:

"He eateth his meat, poor melancholy demon,
He eats not, drinks not, sleeps not, has no use
[illegible]
'Tis of himself."

The conditions most likely to be confounded with mental depression without delusions or hallucinations are hypochondria, hysteria, and eccentricity. In hypochondria there is a concentration of ideas upon the bodily health and abnormal sensations connected therewith. Trifling, but usually actual ailments are magnified and exaggerated, but when the mind is deranged, absurd and impossible maladies are imagined to exist. In the one there is some reason for the ideas, in the other usually there is not. With hypochondria, there is a persistent desire and constant effort made for relief. Doctors and charlatans are consulted. Friends are interviewed, and medical writings are read with avidity, and there is a constant trial of medicinal remedies. In the confirmed depression of genuine mental disease, there is no hope of relief and no effort made except to plan self-destruction. Suicide appears to be the only way out of misery. Hypochondria is afraid of death. Melancholia welcomes it as an escape from trouble. When the hypochondriac becomes so engrossed in ideas relative to his physical condition, that he is unable to entertain and discuss others, and is so far influenced by them that his mode of living is correspondingly changed, either in regard to food, habitation, or employment, or all of these, he has passed the "border land" which divides sanity from insanity, and stands with the unfortunate class that are deprived of their reason.

Hysteria is almost exclusively a disease peculiar to women. The globus hystericus, paroxysmal character, the prevarication and contradictory statements under examination, instability and emotional nature of the depression and the tendency to rapid recovery if left entirely alone, all point to the true nature of the malady.

Genuine eccentricity is not suddenly developed. It may be conveniently considered existing in two types. The first is found with strong individuality, indomitable will, great courage and perseverance, strong convictions, stable ideas, and capability to mark out a path in life and walk consistently therein. While there is a difference from the majority of mankind, the thoughts and actions are in harmony with what they consider the true purposes of life, and the object to be achieved. Their emotions and passions may be strong, but under firm control. The intelligence is clear, and life generally a success. "The singularity of conduct is a natural quality, and not a product of disease." The second type is fond of approbation, desirous of attracting attention, vacillating in ideas and purposes, without much intellectual force or power of application, and with ideas and manners inconsistent with the surroundings and station in life. If these symptoms are late in developing, there is good ground to suspect they are the early symptoms of latent mental disorder. Without doubt there is congenital defect in the most of this class. There is only a short step between them and the vain and frivolous simpleton, whose demented condition makes the laughing stock of society.

The most difficult cases to diagnosticate are those where the natural traits and qualities of character have gradually and almost imperceptibly overstepped the limits of health, and passed into an exaggerated state. It is a condition of magnified morbid intensity of disposition. The change is not so much in "the way of thinking, feeling, and acting," as in the abnormal degree. It differs from

the intensity seen in an outburst of passion, or display of temper by its confirmed and prolonged duration. It differs from health when the power of the will is no longer strong enough to control unreasonable impulses, and also when the judgment becomes so impaired that erroneous views are entertained which previously would have been pronounced false. Occurring in a naturally gloomy disposition, it should be regarded as unsound when the will is so far dethroned that the mind continually dwells on the irrevocable past, or anticipates only future misery. Sorrow and fear enter into every life in varying proportions, but there is also commingled a counteracting amount of joy and hope in every healthy mind.

Confirmed dejection of spirits tends to the formation of delusions, but an insane state is often reached before they are developed. Delusions, hallucinations, and illusions are the concomitants of the disease. The feeling of melancholy may so pervade the mind that the ideas and actions participate in it. The alteration in temper, habits, feelings, affections, propensities, and conduct presents a faithful portraiture of the mental change. The will becomes impaired and the other faculties no longer exert their accustomed force. A knowledge of what is right and proper still exists, but the power to execute is deficient. The judgment becomes biassed, and instead of arriving at a conclusion by the process of reasoning, an opinion is formed from an inward conviction begotten of a depressed condition. That portion of the nervous system which presides over the emotions and intellectual faculties seems to be in a state of hyperæsthesia, while that which subserves the functions of nutrition is in a state of partial anæsthesia. The impressions on the healthy brain, which ordinarily exert emotions of pleasure and promote happiness, may create just the opposite in disease. The amount of mental pain is in proportion to the amount of abnormal sensibility. The obtunding of the nervous centres which subserve nutrition, is manifest by the confirmed loss of appetite, flabbiness of the tissues, and the small amount of strength obtained from the ingestion of even enormous quantities of nutritious diet. The harmonious distribution of nervous force is broken. The over-stimulation of the emotional and intellectual centres is at the expense of those which preside over nutrition. To assist nature in the restoration of the healthy balance is to reëstablish the power of the will, correct erroneous ideas, and restore the natural feelings.

The symptoms of confirmed mental depression depending upon a "diseased condition of the brain, its vessels or investments," are of no ordinary import. They may be the precursors of an attack of profound melancholia or of acute maniacal excitement. It is the opinion of some that all forms of mental aberration are preceded by a longer or shorter period of depression. Whether this is conceded or not, there is no doubt that confirmed dejection of spirits in conjunction with impaired physical health, tends to the formation of delusions which are liable to be accompanied by hallucinations and illusions. The importance of early treatment cannot be over-estimated. In the annual report of the Superintendent of the New York State Lunatic Asylum for 1884, speaking of the discharges for the previous ten years, he says: "During that period there were discharged, recovered, 1440 patients; and of that number, 1231, or 85.48 per cent., had been insane less than one year, while only 209, or 14.52 per cent., had been insane more than one year. It is thus seen that the number of recoveries is six times as great in those who have been placed under treatment before the disease has existed one year, as it is in those who are not placed under treatment until after that length of time."

These figures argue with great force for the early treatment of mental derangement. I know of no one experienced in the care and treatment of the insane, who does not concur in the paramount necessity of early treatment. If the mental faculties are not to remain permanently impaired, the diseased condition must be removed before the integrity of the nervous system undergoes unalterable changes. Not only are the chances of recovery greatly increased by early treatment, but the duration of the disease is also very much lessened. The imperative need of speedy restoration of the afflicted individual to himself, to the society of friends, and to future usefulness in the world, should not be jeopardized by delay.

The successful treatment of the insane consists of much more than prescribing medicine. The deranged can seldom be treated advantageously in their own homes in the early stage of the disease. By removal benefit is not only secured by change of scene probably already unpleasantly associated with morbid ideas, but many sources of irritation and annoyance are also frequently avoided. It is a well-known fact that the insane receive the suggestions of strangers, and comply with their requests more readily than they do the wishes of intimate friends or relatives. The majority of persons deprived of their reason are in indigent circumstances, and are unable to bear the necessary expense of medical attendance and a prolonged stay in a private house reasonably adapted to the needs of their case. To all such the early removal to a well-conducted hospital for the insane should be made. After mental depression becomes established the judgment seldom retains control of the feelings and actions, and the liability to injure self or others is very great. The probability of a sudden change converting a comparatively mild case into a serious one should always be borne in mind. The majority of suicides chronicled in our daily papers come from this class. Hospital care affords such cases the greatest protection and the most liberty. The restraining influence of asylum discipline on the peculiar restlessness and the morbid impulses is less oppressive to the patient than any other. The regularity of institution life, in conjunction with the hygiene of the surroundings, properly prepared food, and judiciously selected diversions, is of no secondary importance. If the proprieties of life are violated by indecent habits, or obscene conduct, the patient is protected by an impenetrable veil between them and a curious and gossiping world.

If the judgment and skill which come from experience and observation of many cases are worth anything it must be accorded to those who have the care and treatment of those in our asylums and hospitals for the insane.

No arguments in favor of boarding or farming out the chronically insane have any bearing on acute cases. In one the storm has passed, in the other it is approaching. If the general practitioner does not desire to assume the responsibility of the case, or is limited in his authority to enforce his recommendations relative to treatment, the interest of the patient will be served best by early removal to an asylum.

A METHOD OF PREPARING POTATOES FOR BACTERIAL CULTURES.

BY MEAD SOUTHER
[illegible]

THE cultivation of bacteria on steamed potatoes in the manner described by Hueppe and others, is objectionable on account of the fact that the cultures cannot be examined closely without lifting the cover of the dish, thus running the risk of infection from bacteria falling in from the air. Furthermore, in examining one culture all other cultures which may be in the dish are exposed. To examine the cultures through the thick glass covers I have always found more or less unsatisfactory. It is, too, extremely difficult to preserve such cultures free from contamination for any great length of time. The preparation of the potatoes, leaving them a half hour to one hour in corrosive sublimate solution, etc., as pointed out recently by Esmarch, is also a tedious procedure. These objections are largely met by using the method introduced by Esmarch, which he has recently described in the *Centralblatt für Bacteriologie und Parasitenkunde*, Band i., No. 1. I have used this method quite extensively, but failed to find in America just such cells as he used.

I recently hit upon the following method, which I am sure will recommend itself, and possesses, I think, advantages even over that of Esmarch, or the method employed by some, of filling test-tubes with potato pap.

The method I recommend is to take wide test-tubes, an inch or more in diameter, and melt them off so as to make a tube about four and a half or five inches long. This length is more convenient, though I have made mine generally from tubes about eight inches long, melting them off in the middle at the blowpipe, thus making two tubes. Pieces of potato about two or three inches long are cut so as to fit nicely in the tubes. It is well to have one end of the potato cylinders cut very obliquely, so as to furnish the greatest possible surface, as in the case of oblique agar or gelatine tubes. I use an ordinary apple-corer to cut the potato, and first cut off the skin at the point of insertion and the point of exit. The tubes may be first sterilized in the air-bath as for gelatine and agar, though this is not necessary, as the tubes with the potatoes in them may be thoroughly sterilized in steam.

Such cultures may be kept indefinitely, and each culture may be examined, etc., without disturbing any other culture, which was unavoidable with the large dishes formerly employed, with several cultures in each dish. A manifest advantage is that the cultures may be studied with the naked eye, and exhibited without opening the tube, just as with agar and gelatine. A few drops of water in the bottom of the tube insure the potato against drying out.

HOSPITAL NOTES.

TREATMENT OF PNEUMONIA AT THE MASSACHUSETTS GENERAL HOSPITAL.

In acute pneumonia, occurring in previously healthy individuals, the treatment employed by DR. MINOT consists in relieving pain and procuring sleep by appropriate remedies when required, with milk or such other liquid nourishment as the patient is willing to take. When the skin is hot and dry, the solution of acetate of ammonia or Dover's powder is ordered. No external applications are made unless the pain should be severe, when weak sinapisms or fomentations are sometimes used. Stimulants are rarely required. In most of these cases little or no medicine is given, the disease being allowed to run its usual course of six to ten days without special interference. The prognosis is almost always favorable.

To patients debilitated by old age, over-work, previous illness, etc., but who are temperate and free from cachexia, alcoholic stimulants and carbonate of ammonia are given as required, with the addition of digitalis should there be signs of pulmonary obstruction from failure of the heart's action; together with nourishing diet. Under this treatment the majority recover, but the prognosis is much more doubtful than in the preceding class.

A third class of patients comprises the cachectic, including the intemperate, the victims of chronic renal disease or of tubercle, etc.; and also those already prostrated by grave acute disease, such as typhoid fever, general bronchitis, etc., although otherwise previously healthy. In these cases stimulants are freely given; large doses of brandy are easily borne, and sometimes appear to save life. Nourishment in liquid form is also required, but it seems less important than alcohol. External applications requiring frequent changing are avoided, the patient having no strength to spare. A large proportion of these patients die, whatever treatment be adopted.

DR. F. C. SHATTUCK believes acute pneumonia to be a general specific disease, of which the pulmonary consolidation is the local manifestation; also, that it is self-limited. The treatment, consequently, is at present purely symptomatic. With the abortion of the disease by large doses of quinine, as has been observed by Flint and others, he has no personal experience. Now and then a case undoubtedly occurs in which, especially early in the course of the disease, venesection is clearly called for, but it has not as yet been his fortune to meet such a case. Pneumonia patients are, as a rule, debilitated to a greater or less degree. Oftentimes the treatment

is comprised in mild counter-irritation to the chest, and an opiate to allay cough, ease pain, and promote sleep. In many cases alcoholic stimulants are demanded, and are given in such quantities as are indicated by the pulse and the first sound of the heart. Digitalis and carbonate of ammonia are also used, though less frequently than alcohol. Sponging of the body with alcohol and water is also prescribed with a frequency which depends upon the temperature and the general condition of the patient.

At the same time, the greatest stress is laid upon careful nursing and judicious alimentation; the bowels are kept open.

MATERNITY HOSPITAL OF PHILADELPHIA.

Service of Barton C. Hirst, M.D.

EFFECT OF RETAINED MEMBRANES ON THE PUERPERAL STATE.

As a commentary on Dr. Fischer's communication in a recent number of the *Vrach*, quoted in The Medical News of January 22d, the following case possesses considerable interest.

A. S., primipara, æt. twenty, was confined July 15, 1886. The labor lasted six hours and was easy. The puerperium was apparently normal in every respect and on July 27th the patient left her bed. Two days afterward the cervix, examined by means of a bivalve speculum, was found slightly torn, but the raw surfaces looked healthy. On the following day, July 30th, the temperature was found in the morning to be 102° and in the evening 102.6°. A large dose of quinine was given.

July 31. Temperature, A. M., 100.6°; P. M., 102°.
August 1. A. M., 101°; P. M., 101°.
2d. A. M., 99°; P. M., 103°.
3d. A. M., 103°.

As the uterus was large and the os patulous, and as a foul-smelling discharge had made its appearance, it was suspected that the high temperature was due to the decomposition of retained membranes, originated by the admission of air to the uterine cavity by the use of the speculum. The uterus was, accordingly, scraped out with a curette, with the result of removing a large quantity of decomposing chorion and decidua. This was followed by an intrauterine injection through a Bozeman's double catheter, of a 1 : 2000 corrosive sublimate solution. On the following day, August 4th, the morning temperature was 99°, the evening temperature 99.4°. August 5th the temperature was normal and so remained.

While, therefore, Dr. Fischer's conclusion that the retention of membranes is harmless, may, in general, be correct, this case just described proves that the admission of air into the vagina by any means, may be followed by the decomposition of the membranes, which can, and probably will produce, unless active treatment be employed, septicæmia or pyæmia.

MEDICAL PROGRESS.

Indications for the Use of Nitroglycerine.—Dr. Trussewitsch, in an instructive paper on the use of nitroglycerine, published in the *St. Petersburg Medicinische Wochenschrift*, points out that the value of this drug in various affections—angina pectoris, migraine, and neuralgia (which he describes as angioneuroses), as also in sea-sickness, some forms of anæmia, faintness, palpitation, and other diseases—depends upon the existence of an irregular distribution of blood, which condition may be inferred from a certain degree of pallor of the skin, especially of the face, often coëxistent with a weak pulse and a small rigid radial artery, which frequently is situated at some depth. When, on the other hand, headache and neuralgia occur in patients with chronic congestion of the subcutaneous veins of the face, nitroglycerine is to be avoided; and similarly it is of no use in asthma, when the face is reddened in consequence of emphysema. If, however, a pale face exists with angina pectoris, migraine, giddiness, shock, toothache, or sea-sickness, the best results may be looked for by giving nitroglycerine. The regulating effect of the drug exercises an influence over the congestion of internal organs similar to that brought about by bloodletting; and in these congestions, whether of lung, brain, or kidney, when they are of a temporary character, the pulse is generally found to be slow and of low tension; a fact which, as the author remarks, is sufficiently well known in reference to the fever-free periods of acute hyperæmia of the lung and kidney. Dr. Trussewitsch lays down as a rule that the condition of the pulse is the best indication for the employment of nitroglycerine, and the most trustworthy guide as to the dose with which to commence the treatment. The smaller the radial artery is, the more rapidly it dilates under the action of the drug, and the less the secondary effects proceed; on the other hand, the fuller the pulse with a distended radial artery, the less it is affected; and finally, the softer the artery, with a weak pulse, the greater the secondary, and the less the general, effects. Single-drop doses of the one per cent. solution are sufficient in cases of small pulse, but with a full pulse it will be found that the full effects cannot be produced with less than two-drop doses. When there is a soft artery with a weak pulse, subnormal doses only should be given—a quarter to half a drop. After the trial dose is given, the patient's sensations of pulsation and pain in the head, as well as the distention of the radial artery under the finger of the physician, will be the guides for increasing the dose. The author finds that the best modes of administering nitroglycerine are the simple dropping of the solution on the tongue, and by means of tablets; much less satisfactory results were obtained when given mixed with water.—*The Lancet*, February 19, 1887.

The German Commission on Vaccination.—By vote of the German Parliament a commission was created in 1883 to consider and report upon the objections to vaccination and antivaccination. This commission was a large one, and included three prominent opponents of vaccination. The following are some of the conclusions given in its report as stated in the *Annales d'Hygiène Publique* for February, 1887:

The length of time for which vaccination protects against smallpox varies greatly in different persons, but in the mean it is about ten years. Revaccination is necessary ten years after primary operation. Two well-marked vesicles are necessary to insure a successful protective vaccination.

There is no evidence as to any increase of special diseases or of general mortality which can be considered as due to the introduction of vaccination.

The use of animal vaccine is preferable. Vaccination should not be performed while scarlet fever, measles, diphtheria, whooping-cough, typhus, or erysipelas is epidemic, or unusually prevalent in the neighborhood. Infants should not be vaccinated before they are three months old, unless smallpox is prevalent in the vicinity.

The greatest care as to the cleanliness and disinfection of the instruments used for vaccinating is insisted on.

PEROXIDE OF HYDROGEN IN WHOOPING-COUGH.—DR. BENJAMIN WARD RICHARDSON, in *The Asclepiad*, No. 13, states that he has treated nine cases of whooping-cough with peroxide of hydrogen exclusively, in six males and three females all children. The solution was given in doses of a fluid-drachm five or six times a day. The remedy in this affection has a decided value. Commencing with it in the acute stages of the disease, and trusting to it alone, he has never seen pertussis cut short so quickly and determinately by any mode of treatment except change of air. He had previously used dilute nitric acid in whooping-cough, as advised by the late Dr. Gibb, and with satisfactory results. The peroxide appears to him to act in a manner very similar, but, he thinks, with more effect. It subdues the spasmodic paroxysm, checks the secretion in the throat, and shortens the period of the malady, lessening, thereby, the dangers of after-effects. The mode of prescribing it is:

Hydrogen peroxide (10 vols. strength) .	℥vj.
Glycerine pure	℥iv.
Water distilled to	℥iij.

Mix. To make a solution of three fluid-ounces, of which let half a fluid-ounce be taken in a wineglassful of water as directed.

When there is stridulous spasm with the cough he substitutes ozonic ether ℥ij for the solution of the peroxide, or adds it to the mixture.

THE INFLUENCE OF VENOUS STASIS UPON THE SECRETION OF URINE.—PANETH, of Vienna, has made a series of experiments on this subject, and finds that a diminution in the secretion of urine occurred when the increase of blood pressure varied between 1.5 and 6.4 millimetres of mercury in the vena cava. Arterial tension diminished moderately after each narrowing of the lumen of the vena cava, but soon became again normal, and when the occluding ligature was beneath the liver, and the portal system was free from obstruction, the tension was normal. The effect of the venous stasis was independent of any consecutive variations in arterial tension. Ludwig had formerly explained the failure of secretion of urine from venous stasis by mechanical compression of the urinary tubules from the distended veins. If this was correct, Paneth thinks that no diuretics could increase a secretion diminished by venous stasis. The following experiment demonstrates the point in question; an injection of nitre causes profuse diuresis to succeed lessened secretion when the arterial tension is kept at a low degree by chloral hydrate.—*Fortschritte der Medicin*, February 1, 1887.

THE ADMINISTRATION OF PHOSPHORUS IN RICKETS.—The administration of phosphorus and of phosphates in rickets has been recommended on the ground that in the diseased bones the earthy phosphates are greatly deficient, and that, introduced into the system, these substances will supply the deficiency. Phosphorus, as is well known from the researches of Wegner, when given to growing animals, renders the developing cancellous tissue of the bones denser than natural, more like the compact tissue; even in adult animals, a similar change takes place. These results are independent, as Wegner showed, of the presence of excess of phosphates, for they occur when phosphates are absent from the food. Although, therefore, the reason for the administration of phosphorus in rickets is well grounded, medical men hold very different opinions as to its utility in that disease. Some have given it with cod-liver oil; as in Kassowitz's phosphorized cod-liver oil, which contains 0.01 per cent. of phosphorus. The objection to this mode of administration is not only that the phosphorus tends to deposit on standing, and thus a variable and even dangerous dose may be given, but it is impossible to say how much benefit (if any) that ensues is due to the oil, and how much to the phosphorus. A better mode of administration has been devised by Hasterlik. Phosphorus (0.01 per cent.) is dissolved in bisulphide of carbon (0.25 per cent.), and one hundred parts of water were added; one teaspoonful is given twice daily, constituting a dose of 0.0001 gramme in the day. The bisulphide of carbon not only acts as a solvent for the phosphorus, but has, according to Dujardin-Beaumetz, a beneficial effect in intestinal catarrh, and might thus be of service in the early stages of rickets. How far this preparation is beneficial in this disease has not yet been sufficiently ascertained.—*British Medical Journal*, February 19, 1887.

TUBERCLE BACILLI IN STRIPED MUSCLE.—OLIVER has carefully examined a case of tuberculosis of the heart-muscles and of the muscles of the back, and has found that the bacilli are in no direct relation with the muscle substance itself. The development of the tubercular progress goes on in the intermuscular connective tissue, and it destroys the normal muscular substance by pressure, atrophy, and the infiltration of the poisonous products of the bacilli.—*Fortschritte der Medicin*, February 1, 1887.

INOCULATION OF TUBERCULOSIS IN A CHILD.—EISENBERG, of Warsaw, reports the following case where tuberculous infection followed the Jewish custom of circumcision, and the application of the lips to the wound to stop hemorrhage.

Two months after circumcision enlarged inguinal glands were observed, and four months after inoculation the child was brought for treatment. The general condition of the patient was good; on the foreskin was an ulcer surrounded by a yellow, deeply infiltrated exudate, and upon the frenulum an ulcer as large as a pea. The inguinal glands had become greatly enlarged, the integument over them was much thinned, and one of the glands had ruptured, giving vent to a watery fluid containing cheesy masses. Behind the left ear there was also a large, fluctuating abscess. The lungs, intestines, and skin were normal. Antisyphilitic treatment

failed to alter the conditions. The child died from erysipelas and extension of the bubœs.

The examination of a portion of the foreskin and matter from the glands revealed the presence of tubercle and bacilli.

The only inference justifiable is that the circumcisor was tuberculous, and that his sputum contained bacilli. Eisenberg cites twelve parallel cases in the literature of the subject.—*Centralblatt für die gesammte Therapie*, February, 1887.

Extirpation of the Spleen.—At the recent Congress of Russian medical practitioners, Dr. A. G. Podrez, privat-docent in Kharkoff, read a paper on extirpation of the spleen, including the notes of a case in which he himself had recently performed this operation. The patient was a woman with ague-cake, associated with ascites and extreme cachexia. The operation was performed on the 22d of November last; the patient subsequently went on well, being able to get up on December 10. The weight increased and the ascites disappeared. On the 16th, however, she had a rigor, and the urine contained a large quantity of albumen and hyaline casts. Death occurred on the 27th, and was due, as shown by the necropsy, to diffuse parenchymatous nephritis. The total number of cases of extirpation of the spleen collected by Dr. Podrez (including his own) is forty-two. Of these, one was performed in 1549 by Saccharelli, and one in 1711. The rest all belong to the present century. If his own case is reckoned as a recovery, the mortality is 73 per cent.; if otherwise, the mortality is 76; the recoveries being twelve or eleven out of the forty-two cases, according as this is or is not reckoned as belonging to that category. The cause of the eleven deaths was septicæmia in one case, peritonitis in one case, and hemorrhage either during or shortly after the operation in all the others. Dr. Podrez thinks that an improved method of performing the operation is required in order to obviate the tendency to hemorrhage. It is also to be desired that, by means of further observations, the indications for the operation in cases of enlarged spleen associated with both ague and leukæmia may be defined.—*Lancet*, Feb. 26, 1887.

Hernia of the Cæcum.—Frederick Treves, F.R.C.S., Surgeon to the London Hospital, in the *British Medical Journal*, February 19, 1887, reports two cases of hernia of the cæcum in a paper of which the following is an abstract.

He comments upon the statement made in most modern text-books in English and French that these herniæ have no sac, and shows that cæcal ruptures are, except in a few instances, always provided with a sac in whose interior the gut is situated. There is also very little evidence to show that the cæcum may descend into the scrotum or crural region entirely bared of peritoneum. In general, museum specimens and unrecorded cases show that the rupture is much more common in males than in females, occurs on the right side, and is practically limited to adults.

In the cases with perfect sacs that part of the cæcum and colon is protruded that would naturally have been free and covered by peritoneum, while in the abdominal cavity. It is to be noted that in these cases the peritoneum that lines the iliac fossa is actually drawn down, as Scarpa believed. This is shown by the fact that the line of reflection of the peritoneum from the colon to the parietes, instead of being about the level of the iliac crest, will be just within the inguinal ring.

An incomplete sac, when it exists, may be formed also in this manner. The cæcum protrudes as a free segment of gut. It alone occupies the sac. Some loops of small intestine now descend, the sac increases, and in its growth drags the peritoneum from the hinder wall of the cæcum.

The cæcum may be protruded alone, or with it may be coils of ileum and omentum. In such cases the cæcum will usually lie to the right, the ileum to the left, and the omentum between the two.

Of the clinical characters of the cæcal hernia there is little to be said. It is usually irreducible or difficult of reduction.

The hernia is frequently in the condition known as that of incarceration or obstruction, and, when so affected, it appears to present no distinctive symptoms. It then compares with a loop of transverse colon obstructed within the sac of an umbilical hernia. The rupture may be strangulated, but this condition does not appear to be so common as that just named.

Treatment of Diphtheria by Pilocarpine.—Dr. Lax has treated a number of patients during an epidemic of diphtheria with pilocarpine, and with very good results. In six weeks sixteen children were attacked by diphtheria; of these the first six had been treated by cauterization with a solution of silver nitrate, three per cent., and gargles of potassium chlorate; the results were four cures and two deaths. The ten other patients were treated exclusively by pilocarpine and all recovered, although some of the cases were very severe.

Under the influence of pilocarpine the mucous and salivary secretion greatly increased; great quantities of diphtheritic membrane were expelled by the throat and nose; respiration became more free; fever disappeared; the children regained appetite, and recovered in from three to five days, at the close of the attack all manifesting a characteristic eruption of herpes labialis. The following is the formula employed by the writer:

℞.—Pilocarpin. hydrochlorat.	gr. $\frac{1}{3}$ to $\frac{3}{8}$.
Pepsinæ	gr. 10 to 12.
Acid. hydrochloric.	gtt. 2 to 3.
Aquæ destill.	$\mathfrak{Z}17\frac{1}{2}$.

Of this mixture a teaspoonful or tablespoonful was taken in wine, and warm fomentations were applied to the throat. At the end of the third day the diphtheritic membrane upon the tonsils and pillows of the fauces had disappeared.

Guttmann has treated in a year and a half eighty-one cases of diphtheria by pilocarpine without the loss of a patient. Gelsner and Dilewshy have also had good results in desperate cases with this treatment. The formula given may be varied as each case indicates, and also its dosage.—*Journal de Médecine*, February 6, 1887.

A Case in which the Urinary Bladder was Twice Ruptured, the First Time by an Injury, the Second Time—Seven Years After the First—by the Giving Way of the Cicatrix.—Mr. Henry

MORRIS, F.R.C.S., reported to the Royal Medical and Chirurgical Society, on February 22, 1887, the case of a man, æt. thirty-six, who had been drinking at a public house on the evening of June 4, 1879, when a struggle ensued, and his opponent threw him and knelt with violence upon his abdomen. All the symptoms of peritonitis and rupture of the bladder were excited, and the patient was admitted into the Middlesex Hospital on June 6, 1879. The treatment consisted of hot fomentations to the abdomen, half a grain of opium in a pill every six hours, and the retention, just within the neck of the bladder, of a gum-elastic catheter. He recovered perfectly, and left the hospital on July 10, 1879.

He applied at the hospital again on August 4, 1886, and gave the following account: On August 2 he had been at a "bean-feast." On the following morning his bowels acted and he passed some urine, but the latter act was attended with some pain. From this time pain increased, and in the evening he was unable to micturate. He vomited frequently, and had had hiccup since the onset of pain, until the afternoon of August 4, 1886, when a catheter was passed and nearly three ounces of bloody urine were withdrawn. He was then admitted as a case of peritonitis and suppression of urine.

On August 5 about one pint of thick, purulent, and slightly blood-stained urine was drawn off. At 7 A. M. on August 6 he passed a little flatus and a large quantity of urine, and suddenly became very sick. Soon afterward he was quite collapsed; his abdomen became very distended; he never rallied, and died at 11.5 A. M. on the same day.

At the post-mortem recent general acute peritonitis was found, and in the pelvis there were fifteen ounces of purulent urine and a quantity of lymph. A band an inch and a quarter long united the fundus of the bladder with the rectum. The vesical end of this band was hollowed out into a slender funnel, and through a rupture in it close to the bladder a string of mucus was projecting. Slight pressure caused purulent urine to ooze from the bladder through the rent into the peritoneal cavity. The rectum, bladder, and penis were removed *en masse*, and were submitted to a committee consisting of Mr. Savory, Mr. Bryant, and Drs. Goodhart and Kingston Fowler, who reported that in their opinion "the specimen exhibits all the features which might be expected at a remote period after a rupture of the bladder."

This case, in the first instance, was reported in 1879 as one of recovery from rupture of the bladder. It is now brought before the Royal Medical and Chirurgical Society because in its completed form it affords conclusive proof that an intraperitoneal rupture of the bladder is not necessarily fatal, but may be recovered from under the simple treatment employed in this case, provided the urine at the time of the rupture is of normal composition. The case is believed to be unique, in that it furnishes us with the post-mortem appearances of the bladder some years after recovery from an intraperitoneal rupture of the coats of that organ.

INFLUENCE OF DRUGS GIVEN TO NURSES UPON THEIR MILK.—SCHLING has made a series of experiments upon this subject, and has reached the following conclusions:

Salicylate of sodium, dose varying from 30 to 45 grains; when the child was nursed in less than an hour after the nurse had taken the drug, the salicylate was not found in the child's urine; it disappeared in 24 hours after administration, and was found an hour after the nurse had taken it. Elimination ceased at the same time with nurse and child.

Iodide of potassium was found in the milk by its characteristic reactions for 24 hours after ingestion. With the child, elimination continued 72 hours; with the mother, 44 hours.

Ferrocyanide of potassium gave a characteristic reaction in the urine of the nurse, and no reaction in that of the child.

Iodoform, when employed upon wounds of lying-in women, produced iodine in the milk and urine of the mother, but not always in the urine of the fœtus.

Mercury was transmitted to the milk of the nurse in but very small quantities, and irregularly; its presence seemed to depend upon the quantity of milk reabsorbed; the common idea that one who is taking mercury must not take acids, was entirely disproved.

Chloral was given in doses which ranged from 25 to 45 grains. This produced a maternal sleep of two hours; there was no effect upon the child. If the infant is feeble, and prematurely born, it is well to wait two hours, but no longer, before putting it to the breast.

Atropine—the sulphate in solution of 1 to 100. Hypodermatic injections of $\frac{1}{12}$th to $\frac{1}{8}$th of a grain produced decided maternal symptoms. Dilatation of the child's pupils followed, which disappeared in 24 hours; it should be employed in very small doses only.

As far as the influence of the febrile state of the mother upon the child was concerned, in the great majority of cases, the milk of a fevered mother had no effect upon the child; in some rare cases of persistent and severe fever, the child's temperature curve resembled that of the mother. Bumm has demonstrated, in a case of mastitis, the passage of micrococci in the milk into the digestive apparatus of the child.—*Journal de Médecine*, February 20, 1887.

TUBERCULOSIS OF THE FAUCES.—MR. L. BROWNE showed at a recent meeting of the Medical Society of London, a young woman, aged twenty, married, and the mother of three children, who was the subject of tuberculosis of the fauces and pharynx, extending to the posterior wall of the larynx and slightly involving the right arytenoid cartilage. The lung condition showed only incipient phthisis, but bacilli of tubercle were plentiful at the seat of ulceration. The patient had suffered on admission into the hospital on December 4th from dysphagia in such an extreme degree that she preferred not to take food. According to the method advised by Krause, of Berlin, the diseased surface, previously anæsthetized by cocaine, was scraped, and solutions of lactic acid, 20, 40, and 60 per cent., were applied daily for twenty-one days. At the end of that period acute inflammation took place, on recovery from which the dysphagia was found to be absolutely relieved. In reply to Dr. Angel Money, he said that the case was regarded as tubercular by all who had seen it, and the typical bacilli were discovered.—*Lancet*, March 5, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM IN ADVANCE . . . . . $7.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 19, 1887.

THE RADICAL CURE OF HERNIA.

IN *The Medical Record* for March 5, 1887, may be found a valuable paper by R. F. WEIR on the cure of reducible and irreducible hernias by Heaton's method of injection, and by the direct modern operation. The treatment by injection of various fluids has been comparatively seldom practised, and its merits have rarely been tested on an extended scale by competent observers. Hence, the procedure is, as a rule, dismissed with a few words in our treatises and text-books on surgery, and has been unfairly condemned.

The method of Heaton, as is well known, consists in throwing into the connective tissue of the inguinal or femoral canal, after the reduction of the rupture, from ten to twenty minims of a mixture composed of half an ounce of fluid extract of white-oak bark, thickened by the addition of fourteen grains of the solid extract of the same bark, and containing half a grain of morphia. Weir has performed the operation in 72 cases, all but 8 of which were inguinal hernias. Of the 64 inguinal hernias, the further history of the patients was traced in 35 cases, in 12, or 33 per cent., of which a cure was obtained. Adding to these the 36 cases, with 9 cures, recorded by Gay and Bull, 71 cases afford 21 cures, or a percentage of 29.5. This rate of success, along with the safety of the procedure, certainly justifies the conclusions of Weir that it is especially adapted to small reducible ruptures both of children and adults, and to recurrences after the failure of the open operation. In the latter class of cases the protrusion is usually small, and it sometimes happens that the treatment can be carried out without interrupting the vocation of the patient.

By far the larger number of ruptures which fall under the notice of the surgeon are unfitted for the treatment by injection, so that the practice of the present day is to resort to the modern open operation in old reducible hernias, in which bulk, discomfort, pain, temporary incarceration, or the interference with the usefulness of the patient call for aid. This operation consists, first, in exposing the sac and reducing its contents; secondly, in isolating the sac, ligating its neck, and removing the fundus below the point of ligature; thirdly, in pushing the stump into the abdominal cavity; and, fourthly, in approximating the refreshened edges of the ring with sutures. As the late Professor Gross was the first, in 1861, to suture the pillars of the ring, and Riesel was the first, in 1877, to ligate the sac and excise its fundus, the procedure may be entitled the Gross-Riesel operation, of which other surgeons have made some modifications, particularly in regard to the treatment of the exposed sac. These modifications are intended to lessen relapses, which are due to the weakness of the cicatrix in the serous membrane.

Among the improvements in the management of the sac, the following may be mentioned, in all of which the sac is merely separated from its connections, and not cut away. Obliteration of the serous surfaces by a row of sutures, practised by Hahn; torsion of the fundus of the sac, after ligating its neck, and transfixion of the sac by the intercolumnar sutures, to prevent its untwisting, as devised by Ball; ligation of the neck of the sac, along with the transversalis fascia, and intercolumnar suture of the sac, as in the preceding method, instituted by Hardie; and wrinkling up of the sac, or throwing it into a series of transverse folds, by transfixing it with a catgut thread, through which the internal ring is blocked, as devised by Macewen. In addition to these modifications, Southam ties the sac, with its included omentum, with a double ligature, cuts off the lower portion, and leaves the upper portion to act as a plug which prevents the redescent of the gut. Of these various methods of managing the sac, that of Macewen has given the best results, as 25 cases of free inguinal hernia show only 9 relapses, a percentage of 36 per cent., and 23 cases of strangulated inguinal and femoral hernias afford only 1 relapse, or a percentage of 4.3.

In estimating the value of the modern direct operation, the questions of recurrence and of mortality must be considered. In a general way it may be said that relapse occurs in about one-fourth of the cases; but it must also be stated that in four fifths of the failures there is a marked improvement, the protrusion being slight, with little tendency to increase, and readily controlled by a truss. Of 379 operations for free or non-strangulated inguinal hernia, collated by Weir, 16, or 22 per cent., perished,

and if from these be deducted the deaths from preventible hemorrhage—increased experience having taught how this may be avoided—the mortality is reduced to 2.9 per cent. Of the 36 operations for femoral hernia, all recovered.

From the facts presented by Weir, we may conclude that Heaton's operation can be safely resorted to in small reducible hernias, with a fair prospect of success; and that painful, unmanageable, or irreducible protrusions, which render life miserable, or unfit the subject for gaining a livelihood, should be met by the modern direct operation.

THE TREATMENT OF PNEUMONIA.

THE daring experiments of Hughes Bennett, Skoda, and Deitl, placed the treatment of pneumonia on a rational basis by making a knowledge of the natural history of the disease the starting-point for medication. Thirty or forty years ago it required no little courage to treat cases of pneumonia without bleeding and antimony, but as a result of the teachings of the Edinburgh and Vienna schools, the expectant or symptomatic method of treatment has gradually replaced the more active antiphlogistic plan of the past generation. To this has contributed in no small measure the growth of a belief that pneumonia is a specific, self-limited disease, of which the lung trouble is only a local manifestation.

We have presented our readers, in this and the two preceding numbers of THE NEWS, with a summary of the plans of treatment pursued in the leading hospitals of Philadelphia, New York, and Boston, and on looking over it one is struck with the uniformity in principle underlying the varying details. In each instance the plan followed is essentially *symptomatic*, and, where not expressly stated, it is tacitly admitted that we have no specific remedies against this disease. Cases of moderate severity do well with little or no medication, while the severer forms demand measures which allay fever and support the strength, systemic and cardiac.

It is interesting to note how little stress is laid upon the value of arterial sedatives as aconite and veratria, both of which are still extensively used and specially relied upon in this disease by practitioners throughout the country. While of undoubted benefit in the early days, if employed indiscriminately and during the entire attack they may be harmful. We believe, however, that the more robust subjects in country practice stand these remedies better than the debilitated patients of the city, and more particularly of hospitals.

Upon the question of bleeding we should have liked fuller details as to indications and the frequency with which it has been employed at the different clinics. We are firmly persuaded that there are many fatal cases each year which venesection might have saved. The conditions which call for it are those laid down by Dr. Bartholow—"at the outset, in a vigorous subject, when congestion is increasing in depth and extent; and at the approach of the crisis, when the heart labors in consequence of overfulness of the veins and ischæmia of the arteries." The inhalation of oxygen recommended by Dr. Loomis in the œdema, has an important use whenever, as shown by the lividity, the blood is imperfectly oxidized.

With the recent endeavors to bring pneumonia into the category of parasitic diseases, we have attempts to establish an anti-parasitic plan of treatment, but so far without any special success. It may be, however, that to the generation which will follow at the hospitals the men whose practice we have given, the symptomatic and expectant plan at present in vogue will appear as crude and unscientific as does to us the active antiphlogistic treatment, with venesection *coup sur coup* and antimony to repletion.

SUDDEN DEATH FOLLOWING LABOR.

THE general sentiment of humanity does not accord with that of the Roman emperor, who, when asked what death was the most desirable, replied that which is the most sudden. Desirable as such a death may be for the individual who, with scarce the interval between the lightning's flash and the thunderbolt, departs, it is not desired by those who witness it. But there is a class of cases in which this sudden ending of life must be very sad for the individual, if time permit reflection, while it overwhelms the nearest relatives; the mother, "when she feels for the first time her first-born's breath," when a new and the strongest of earthly ties must be suddenly sundered, naturally above all others, shrinks from departure; and should she die, there is a profounder sorrow than when death occurs under almost any other conceivable circumstances.

Probably the most frequent cause of sudden death following labor is uterine hemorrhage, and many instances have been recorded where the so-called flooding has been fatal; fortunately, death from this cause can in a large number of cases be prevented by timely and intelligent professional care. Eclampsia, pulmonary embolism, the entrance of air into the uterine veins, nervous exhaustion, and heart-failure are also causes. Another cause has recently been suggested, but we think without just ground, in the report of a case published in the *Journal d'Accouchements* of the 15th of February.

The case was reported to the Medical Society of Amiens by TRÉPANT, surgeon to the hospital of Nesle. A woman, thirty years of age, of good constitution, and who had previously given birth to two

healthy and living children, had in each of these labors a hemorrhage which threatened her life, and the accident was followed each time by serious and protracted metro-peritonitis. Three years and a half after the second labor the third pregnancy occurred; during this her general condition was good, and there was no cardiac or renal disorder, but she was very apprehensive of danger in connection with delivery of the placenta. Her labor was easy, somewhat rapid, and she was delivered of a living child; immediately after the birth of the child nine grains of ergot were given, and the expulsion of the placenta soon followed, but was attended with a slight loss of blood which was readily arrested, a second dose of ergot being given. After the completion of the toilet of the external genital organs, she was removed from the couch upon which she had been confined, and placed in bed; her expression was good, the uterine contractions were quite manifest, the uterus was well retracted, the pulse was full and regular, she was contented and happy, and wished to see her baby.

Her condition was so favorable that the accoucheur was preparing to leave, when she suddenly exclaimed she could not see, and this was followed by paroxysms of tossing her arms and restless movements, with plaintive outcries. There were no convulsions, and no rigidity of the muscles; the face was not swollen or discolored, there was no frothing at the mouth; the pulse was normal and rather full, the uterus well contracted, and there was neither internal nor external hemorrhage, but the skin became cold; the respiration was rapid, and intelligence perfect; she complained of a feeling of oppression and difficulty of breathing, and especially of her inability to see; she vomited a little fluid which was discolored by the ergot. She lived three hours and a half, during which time occasional remissions in the severity of her symptoms occurred, and she died from well-marked asphyxia.

Trépant, in speculating upon the probable cause of death, suggests that it was ergot, there possibly being a peculiar susceptibility to it, for the quantity of the drug given was but little more than fifteen grains. But here we have one weak hypothesis, that of an extraordinary idiosyncrasy, to sustain another of like character. It is hardly possible that a fatal result could occur in a few hours from the quantity of ergot employed, nor were the symptoms those of ergot poisoning.

No post-mortem examination was made, and while even after it the cause of death might have remained unknown, yet it would have negatived certain possible hypotheses. Some of the symptoms closely point to hemorrhage, and this hemorrhage may have been from rupture of an abdominal vessel, or from rupture of the uterus. Again, the hypothesis of nervous exhaustion cannot be entirely excluded, for while dimness of vision is so characteristic of post-partum hemorrhage, yet it is possible for it to be present in the condition previously suggested. We are disposed to think that the patient's mental condition may have contributed to the fatal issue. It would be quite rational to suppose that the fear of dangerous hemorrhage, which she had entertained during pregnancy, would readily recur when unexpected blindness and prostration were manifested—symptoms the significance of which, doubtless, she knew too well from her previous experiences—and this fear assist in making the depression greater.

But whatever interpretation of the etiology of the fatal result be given, the case is a warning to the obstetrician to be ever watchful so as to ward off any danger of death to the puerpera which may plainly be presented, and also to be prepared for the possibility of witnessing, in very rare cases, this sad event without being able satisfactorily to explain its cause.

HEPATIC PHLEBOTOMY AND PUNCTURE

At the Brighton meeting of the British Medical Association George Harley read a paper on "Hepatic Phlebotomy," in which he urged the propriety of abstracting blood directly from the liver in cases of congestion or inflammation. The communication appears in the *British Medical Journal* of November 13, 1886, and in the issue of January 15, of this year, he again takes up the subject. In several of the recent numbers there has been a lively discussion between Dr. Harley and certain army surgeons as to priority in this procedure. The case in which this operation was performed was one with an enlarged and indurated liver, the result of hepatitis. The lower part of the body was anasarcous, the abdomen was filled with fluid, and in spite of all methods of treatment, including tapping, the patient was, when first seen by Dr. Harley, in a perfectly hopeless state. The upper part of the liver was pierced with an eight inch long trocar, of a diameter between a No. 2 and No. 3 English catheter, which was thrust in up to its hilt. On withdrawing an inch or two, a stream of blood immediately issued, and twenty ounces were abstracted with the greatest benefit. From the day of the operation the liver became reduced in size, and, with the aid of tapping and the administration of the resin of copaiba, the ascites and general anasarca disappeared in about two months, and the patient made a good recovery.

It seems clear from the discussion which has taken place that McLean, of the Army Medical School, at Netley, has long advised direct depletion of the liver, and some of his pupils have resorted to it with benefit in cases of engorgement of the liver. It is by no means always a harmless procedure, as a case is recorded by Boyes Smith in which fatal

hemorrhage into the abdomen followed the exploration of the liver for abscess. As a rule, however, very little blood comes during aspiration of the liver, and we agree with Surgeon Major Quill when he says that "the possibility of abstracting eighteen or twenty ounces of blood from the liver is quite exceptional; more commonly five or six ounces, or frequently not even an ounce can be obtained."

Harley also recommends puncture of the capsule of Glisson as a remedial measure in cases of congestive hepatic hypertrophy, and gives two cases in which benefit followed the operation. The punctures, from three to six in number, are made in the anterior parts of the liver, in the right or left lobe, according to which is the most gravely affected. The trocar is withdrawn and the canula left in the wound for a few minutes, to permit of the oozing of any liquid. This is a method which has long been followed by the Chinese, who use, however, solid acupuncture needles, but the effect is practically the same.

It is difficult to say just how far these measures can be recommended. The experience of army surgeons seems favorable, and these papers have served to bring out some very interesting points in their practice. We have so little faith, however, in the efficacy of this method, that Harley's suggestions seem to us to require strong backing, and we shall look with interest for further accounts of this plan of treatment.

The Kings County Medical Society has just made arrangements for the purchase of a piece of property, No. 336 Bridge Street, Brooklyn, and it will there take up its abode after May 1st. It consists of a private house, with sufficient ground in the rear to accommodate a future extension when that shall become necessary; the cost was not far from $10,000. The trustees of the building fund, Drs. Thallon, Matheson, Jewett, Hunt, and Hutchins, have authority from the Society to collect and apply to the property $5000 more than the cost, for the equipment of meeting-rooms and library within this new home of medicine.

M. Duclaut, Professor of Biological Chemistry at the *Faculté des Sciences de Paris*, and one of the most distinguished pupils of M. Pasteur, has just brought out a journal which is to be specially devoted to gathering all information concerning microörganisms. The name of the new journal is *Annals of the Pasteur Institute*. It is to be regretted that this title appears to lend a somewhat limited character to M. Duclaut's journal, for the editor, we are informed, fully intends publishing all articles of value that may be contributed, whether they emanate from M. Pasteur's laboratory or elsewhere.

The first number contains an important letter from M. Pasteur on rabies, in which he treats the question from his own point of view, and a paper of MM. Nocard and Roux, upon the cultivation of the bacillus tuberculosis.

We are confident that this publication will meet with the success it deserves, for it, with the recent *Centralblatt für Bacteriologie*, supplies a want that has been markedly felt amongst our scientific publications.

Dr. Abbott, of the Massachusetts Board of Health, reports the results of his investigation into the origin of recent cases of smallpox among the workers at the paper-mills at Holyoke. He traces the cases to imported linen rags that had passed through the New York Custom House, and were marked "disinfected." This fact may be expected to arouse attention to the present system of treating foreign rags, and to reopen the discussion of their fumigation at the seaports, which last year gave the Treasury Department so much trouble.

The Supreme Court at Washington has handed down a decision that an insane person who takes his own life does not "commit suicide," and that life insurance may be recovered even though the policy may provide that it shall be void if the insured person shall die by suicide: self-killing by a lunatic person is by law to be regarded as an accidental death.

Dr. William Goodell resigned last Tuesday the post of Physician-in-Charge of the Preston Retreat at Philadelphia, which he has held for twenty-two years. Dr. Joseph Price was elected as his successor.

At the twenty-sixth annual commencement of the Bellevue Hospital Medical College, of New York, held on Monday evening, the degree of M.D. was conferred on one hundred and thirty-four graduates.

At the fiftieth annual commencement of the University of Louisville, held on March 1st, the degree of Doctor of Medicine was conferred upon eighty-seven graduates.

SOCIETY PROCEEDINGS.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, February 28, 1887.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. I. N. Kerlin read a paper on

MORAL IMBECILITY.

The histories of four children were presented: the first was illustrative of the incipient prostitute; the sec-

ond of the incipient burglar; the third, a religious hypocrite and egotist; and the fourth a confirmed juvenile tramp and incipient confidence man.

The first case was one which had been reported by Dr. J. C. Carson, of Syracuse. E. P., aged fourteen years, was admitted to the New York Asylum for Idiots, March 6, 1886. She presented no special peculiarities in appearance, and was described as disobedient, obstinate, very passionate, and a little given to pilfering. At the age of eight years she had been adopted into a respectable family. Nothing of any consequence could be obtained with reference to her antecedents. When brought to the Asylum, she acknowledged that she had quarrelled with the folks at home particularly about church and school matters. She stated that she understood the purposes of the institution, and declared that she believed that she had the worst temper of any person in the world, but she did not think that she was "a fool or an idiot." For a week she did well. After this scarcely a day passed without trouble between herself and others, or between others brought about by her instigation. She finally caused so much trouble that it was found necessary to remove her to another institution. The case was reported by Dr. Carson to show how closely the insane condition could be approached and maintained, and yet not really exist. Neither was she in any sense imbecile, unless *morally* so. There was a partial loss of self-control and such irritability of temper and tendency to go wrong that for her own interests and protection, as well as that of society, there can be no question that she required custody of some kind. She had reached a time of life when some restraint upon her liberty was absolutely necessary to save her from ruin or insanity.

The second case was that of Tom McK., aged twelve years, who was admitted to the Training School, at Elwyn, November 9, 1886. He was described as incorrigible. There was nothing in his appearance to suggest unlikeness to normal boyhood. He was but little more backward in his studies than would be any neglected boy. He was full of mischief and deceit. The boy promptly responded to school instruction and during the succeeding four years made fair progress. Throughout the seven years of his pupilage, however, there were seizures of irritability and excitement occurring periodically and of increasing intensity, the longer he remained in the institution. He was then discharged. Within six months of his discharge, he had been arrested and had been found guilty of two or more petty burglaries. This incorrigible moral imbecile was the son of a man of the most abandoned character. His mother was recently discovered in the insane department of a county-house, one of the saddest of dements.

The third case was that of G. L., admitted July 12, 1883, a sweet-faced, intelligent, lovable boy, whose gentle manners instinctively won confidence, and made his new-found friends at the institution believe that the boy had been improperly sent there by a mother too eager to relieve herself of the proper relations to her own child. The boy was described as kind-hearted, quick-tempered, very dull of comprehension, fond of working with tools, not malicious, but destructive. The boy seemed to do well for three months. Notwithstanding the good opinion of his teachers, he was an object of aversion to the boys with whom he was associated. He devoutly knelt at his bedside every night and stood well in the Bible class. On a quiet Sunday afternoon the carpenter shop connected with the institution was found to be in flames. After a careful examination, the evidence pointed to one of two or three boys. As a result G. was placed in confinement with the hope of eliciting some confession from him. Through three weeks the boy held out against all persuasion and the authorities were about to give up when, in a letter to his mother, he confessed that he had started the fire to see how the fire machines were used. It was afterward learned that he had fired his mother's house on one occasion. The boy was then placed in the House of Refuge, where he played his *rôle* of sweetness so well that it was sincerely believed that the confession had been a forced one.

The etiological history of this case is interesting. The paternal grandmother was a fanatic on the subject of religion. The eldest son of this grandmother believes that he lives without sin, and the boy's father is of the same belief and has been at all times deranged on the subject of religion.

The fourth case was that of F. L., aged twelve years. He had attended school in the winter and in summer had worked on a farm. He could read fairly well, and write an intelligible letter. Scarcely a symptom of intellectual or moral infirmity had been discerned in this boy, when, without known reason, he eloped. Writing to his father, the reply was received that he had spent hundreds of dollars in bringing him back from just such escapades. A few months later a newspaper was sent to the Institution from Escanaba, Mich., relating the history of a boy who had appeared in that town and had excited much interest. This boy proved to be the runaway. He was returned to the Institution. At the end of six months he again left for parts unknown. After some months he was again returned from Chicago. Again, without reason, he suddenly eloped, and is at present somewhere within a radius of fifty miles of the Institution, occasionally appearing to acquaintances, but mysteriously fading away.

Dr. H. C. Wood said whether we call these cases examples of moral imbecility, or give them some other name, we must recognize that there is a depravity which is the result of heredity or some imperfect development of the nervous system. Recently he had under his notice a case which parallels those reported by Dr. Kerlin. A woman, belonging to a respectable family, went astray at a very early age, and became the mistress of a married man, bore eight children, and died a drunkard in the gutter at the age of twenty-eight. Of the eight children, all, with the exception of one, died in infancy. At the death of the mother, this child, a girl, was taken by a friend, who endeavored to train her in a respectable manner. The attempt seemed to be successful until the age of thirteen was reached, when, three months before the appearance of menstruation, she ran away, and was found in a house of prostitution. Since then her history has been a constant effort to save her, and a constant return to bad sexual habits. It finally became necessary to place her in the House of Refuge. There was no tendency to drink in this instance, so that the love of liquor had no part in the precocious overpowering sexual desires.
